Accepted for publication 28 November 2011

Collagen is the predominant structural protein in tendons and ligaments, and can be controlled by hormonal changes. In animals, injections of insulin-like growth factor I (IGF-I) has been shown to increase collagen synthesis in tendons and ligaments and to improve structural tissue healing, but the effect of local IGF-I administration on tendon collagen synthesis in human has not been studied. The purpose of this study was to study whether local injections of IGF-I would have a stimulating effect on tendon collagen synthesis. Twelve healthy nonsmoking men (age 62 ± 1 years (mean ± SEM), BMI 27 ± 1) participated. Two injections of either human recombinant IGF-I (0.1 mL Increlex®) or saline (control) into each patellar tendon were performed 24-h apart, respectively. Tendon collagen fractional synthesis rate (FSR) was measured by stable isotope technique in the hours after the second injection. Simultaneously, interstitial peri-tendinous (IGF-I) and [procollagen type I N-terminal propeptide (PINP)], as a marker for type I collagen synthesis, were determined by microdialysis technique. Tendon collagen FSR and PINP were significantly higher in the IGF-I leg compared with the control leg (P < 0.05). In conclusion, local IGF-I administration can directly enhance tendon collagen synthesis both within and around the human tendon tissue.

Tendon and ligaments play an important role for the force-transmitting function of the muscular–skeletal system, and collagen represents the most common and structural important protein in these structures (Finni et al., 2000). The regulatory role of different hormonal growth factors and cytokines in humans in relation to stimulation of tendon and ligament synthesis is not fully clarified (Kjaer, 2004), but a rise in expression and tissue content of insulin-like growth factor I (IGF-I) is found to be associated with a rise in tendon collagen synthesis after mechanical loading (Langberg et al., 1999; Miller et al., 2005; Heinemeier et al., 2007; Olesen et al., 2006b). Furthermore, a stimulating effect of IGF-I on collagen synthesis in tendon/ligament tissue is supported by in vitro studies, which have shown that IGF-I directly stimulates fibroblast proliferation and synthesis of extra-cellular matrix proteins (e.g., collagen) in tendon and ligament explants (Abrahamsson et al., 1991a, b; Abrahamsson & Lohmander, 1996; DesRosiers et al., 1996; Murphy & Nixon, 1997). Thereby, IGF-I injections promote tendon and ligament healing in animals after collagenase-induced tissue atrophy (Dahlgren et al., 2002) or ligament disruption (Kurtz et al., 1999; Provenzano et al., 2007). In humans, muscle collagen expression is positively correlated to muscle IGF-IEa expression in patients with acromegaly and growth hormone (GH) deficiency (GHD) (Doessing et al., 2010b). Finally, after systemic GH administration for 14 days, human data have demonstrated an increase in circulating IGF-I and expression of IGF-I in tendon tissue and an accompanying rise in tendon collagen mRNA expression and tendon collagen synthesis in young healthy individuals (Doessing et al., 2010a). The later finding supports a potential regulatory role of the GH/IGF-I axis upon tendon collagen synthesis in humans, but neither provides any direct proof for a causative effect nor is able to identify whether IGF-I or rather GH is the regulating factor for collagen synthesis in human tendon. Thus, the present study was designed to test the hypothesis that local IGF-I administration induces an elevation in collagen synthesis in human tendon tissue.
Subjects and methods

Subjects

Twelve healthy men [62 ± 1 years (range 55–70 years); weight: 88 ± 3 kg; height: 181 ± 1 cm; body mass index (BMI): 27 ± 1; body fat %: 28 ± 1%; and maximal oxygen uptake (VO2max, est): 35 ± 2 mL O2/min/kg] were enrolled in the study. The local Ethics Committee for Medical Research in Copenhagen (H-B-2009-032) approved the protocol. Prior to inclusion, informed written and oral consent was obtained from each subject according to the Declaration of Helsinki. Each subject underwent a medical evaluation, including routine blood tests, and underwent body composition evaluation and had their maximal exercise capacity tested. Exclusion criteria for participation in the study were diabetes, obesity (BMI above 30), smoking, skeletal muscle diseases, hypermobility, previous or present knee injuries, medicine with a potential effect on connective tissue, and screening blood samples values outside normal range.

Health examination and screening

One to 3 weeks prior to the experimental days, the subjects underwent health examination and screening procedures, which included questionnaires about disease and training history, blood samples, and height, weight and skinfold measurements. Blood samples were analyzed for plasma concentrations of creatinine, creatine kinase, calcium, c-reactive protein, basic phosphatase, aspartate aminotransferase, alanine transaminase, erythrocyte volume fraction, sodium, potassium, blood concentrations of hemoglobin (Hb), thrombocytes, leucocytes, and HbAlc and serum concentrations of thyroid stimulating hormone. Fat mass (%) was determined by the skinfold technique. Estimated maximal oxygen uptake (VO2max, est) was estimated by a 10-min two-step submaximal bike test. The workload was increased once after 6 min and the heart rate registered when it was stable.

Study design

The study was designed as a placebo-controlled, double-blinded study comparing effects of a two local injections of either IGF-I or saline (control) on tendon collagen synthesis. In the morning at day one of the experiment, one bolus of IGF-I was injected into the patellar tendon of one leg and a similar volume of saline was injected into the contralateral patellar tendon. The following morning, the procedures were repeated. During the subsequent hours, tendon collagen synthesis was measured directly by stable isotope incorporation and indirectly by microdialysis technique (Fig. 1).

Experimental days

On each of the two experimental days, each subject attended the laboratory at 8:00 h after an overnight fast. No strenuous physical exercise was allowed 2 days preceding the experimental days to ensure that mechanical loading caused no stimulation of tendon collagen synthesis. The delay from the injection of IGF-I until a stimulation of tendon collagen synthesis potentially could be detected was not known. After acute exercise, we have observed an increase in tendon fractional synthesis rate (FSR) a few hours after exercise, peaking 24 h post-exercise (Langberg et al., 1999; Miller et al., 2005). Thus, there may be a time lag from the time of IGF-I injection until a stimulating effect on tendon collagen FSR can be measured. If it mimics the time lag from the end of acute exercise to the enhancement of tendon collagen FSR, one injection of IGF-I 24 h before measuring tendon collagen FSR would be the most appropriate. Nevertheless, the response time might also be shorter. Thus, as the main purpose of the present study was to explore whether tendon collagen FSR can be stimulated by administration of IGF-I locally in the tendon tissue, two injections of IGF-I both 3 h and 24 h after the measurements of tendon collagen FSR was performed to reduce the risk of overseeing a positive effect of the IGF-I administration.

The two local injections of recombinant human (rh) IGF-I (each 1 mg corresponding to 0.1 mL INCRELEX®, Tercica Europe Ltd., Dublin, Ireland) into the patellar tendon were performed randomly between subjects into either the dominant or nondominant leg. Saline (control) was injected into the contralateral patellar tendon. The injections were performed under ultrasound guidance 1 cm distal from the distal patella tip. At day one of the experiment, the subjects rested in bed for 1 h after the IGF-I and saline injections to minimize the disappearance of the infused IGF-I from the tendon area. The following day, the IGF-I and saline injections were repeated in the same leg, respectively, as on the previous day. After the second bilateral injection the subjects stayed in bed and fasted until the end of the experiment. The subjects were allowed to drink water freely throughout the period.

We wanted to inject as high a dose of IGF-I to ensure the stimulation of tendon collagen synthesis; on the other hand, we did not want to enhance circulating IGF-I and thereby transfer the effect of the IGF-I injection to the contralateral control leg. The recommended dose of IGF-I administered to children with primary IGF-I deficiency is two daily injections of 0.04–0.12 mg/kg each. Assuming a body weight, as the subjects in the present study (average body weight: 88 kg), would correspond to a treatment dose between 7 and 21 mg per day. Assuming the knee region corresponds to 2 kg would result in a dose between 0.16 and 0.48 mg per day. Based on these calculations and our concerns regarding enhancement of circulating IGF-I, we chose a dose of 1 mg IGF-I per injection per day.

IGF-I and saline injections

Because this is the first time IGF-I is injected into human patellar tendons with the purpose to raise tendon collagen synthesis, the delay from the injection of IGF-I until a stimulation of tendon collagen synthesis potentially could be detected was not known. After acute exercise, we have observed an increase in tendon collagen synthesis measured by stable isotope technique

Measurement of tendon collagen FSR were performed according to previously applied approaches (Babraj et al., 2005; Miller et al.,...
Effect of IGF-I on tendon collagen synthesis

All blood samples were taken from a cubital vein into sealed vials. After separation by centrifugation, serum was stored at \(-80^\circ\mathrm{C}\) until analysis. A serum sample collected 1.5 h after the last injections was used for analysis of circulating IGF-I. Tendon dialysate collected 2.5 to 3.5 h after the injections was used for analyses of IGF-I. Serum IGF-I and tendon dialysate IGF-I were determined by time-resolved immunofluorometric assay after acid–ethanol extraction, as previously described (Frystyk et al., 1995). All samples were measured in the same assay run (intra-assay CV\% < 5\%).

Statistical analysis

Data are presented as median and range for interstitial IGF-I, whereas all other data are presented as mean ± standard error of the mean. Nonparametric statistics (Wilcoxon signed-rank test) was used to test for difference in interstitial IGF-I between IGF-I leg and control leg because data were not normally distributed. Student paired t-test was used to test for differences between the legs for the remaining parameters. The level of significance was set at \(P < 0.05\).

Results

The interstitial tissue concentration of IGF-I determined locally in the peritendinous tissue in front of the patellar tendon 1–2 h after the last injections was higher in the IGF-I leg compared with the control leg in all subjects [median 7.95 (range 0.20–50.34) mg/L vs 0.01 (range 0.00–0.05) mg/L, \(P < 0.05\)] and also much higher when compared with the circulating IGF-I (0.31 ± 0.02 mg/L, \(P < 0.05\)).
Tendon collagen FSR was significantly higher in the IGF-I leg compared with the control leg (0.051/0.005 vs 0.041/0.005%/h, \(P<0.001\)) in the period from 1.5 to 4.5 h after the last injections (Fig. 2(a)). The increase in tendon FSR was evident in all 12 subjects; however, the size of the increase was different (Fig. 2(b)).

Similar to tendon collagen FSR, the indirect marker for type I collagen synthesis, (PINP) in the peritendinous tissue, was significantly enhanced 2 to 3 h after the last injections in the IGF-I leg compared with the control leg (103 \(\pm\) 21 vs 60 \(\pm\) 12 \(\mu\)g/L, \(P<0.05\)) (Fig. 3). Analyses for PINP and IGF-I in the dialysate were performed on samples from 11 subjects (paired samples), because of catheter diffusion problems in one of the microdialysis catheters in one subject.

**Discussion**

The novel finding in the present study was a significant increase in tendon collagen synthesis rate after local injections of IGF-I into the patellar human tendon compared with the injection of saline in the contralateral tendon of the same individual. The size of the enhancement of the synthesis rate was variable between subjects. This could be due to difficulties in obtaining the tendon biopsy exactly in the injection site. Nevertheless, a significantly higher tendon collagen synthesis rate after IGF-I injections measured by both methodological approaches in this study. On one side, the use of the stable isotopes to determine changes in the tendon tissue as well as by using the microdialysis technique to evaluate collagen synthesis peritendinously (Langberg et al., 1999), it was confirmed that IGF-I administration has a direct stimulating effect on collagen synthesis in human connective tissue.

IGF-I is not only synthesized and secreted to the circulation from the liver, but is also expressed and synthesized locally in tendons and ligaments (Tsuzaki et al., 2000; Olesen et al., 2006a). In healthy human subjects, an enhanced IGF-I mRNA expression has been observed in tendon tissue after systemic GH administration simultaneously with an increase in tendon collagen expression and synthesis (Doessing et al., 2010a). Furthermore, in patients with acromegaly and GH deficiency, positive correlations between local IGF-IEa mRNA expression and muscle collagen I and III mRNA expression have been observed (Doessing et al., 2010b). These earlier findings, together with the present results, support a regulatory role of local IGF-I on collagen synthesis. Fur-
thermore, a stimulating effect of local IGF-I administration on collagen synthesis is in agreement with the previous results from in vitro and animal studies. Administration of IGF-I to canine anterior cruciate ligament fibroblast has been shown to enhance collagen production and type I to III collagen ratio (DesRosiers et al., 1996), whereas administration of anti-IGF-I antibody eliminated most of the mitogenic activity in avian tendon tissue (Tsuzaki et al., 2000).

In physiological situations, like in response to mechanical loading, an association between an enhanced synthesis and release of IGF-I and a simultaneous increase in tendon collagen expression has been observed in animals (Heinemeier et al., 2007; Olesen et al., 2006b). In human subjects, only a few studies have measured IGF-I in the interstitial fluid in peritendinous tissue at rest and in response to acute exercise. In the present study, the concentration of peritendinous IGF-I in the control leg corresponded to what has previously been reported peritendinous during rest (Hansen et al., 2008). No significant change in peritendinous IGF-I was detected in previous studies in response to acute exercise, despite that tendon collagen synthesis was enhanced (Miller et al., 2005; Olesen et al., 2006a). However, no measurement of tissue concentration of IGF-I within the tendon tissue was performed in these studies. Thus, it cannot be ruled out that mechanical loading enhance IGF-I mRNA expression and production within the tendon and thereby stimulate collagen synthesis within the tendons. The present data support such a role, and the increase in tendon collagen FSR in the present study corresponds to the increase, which has been observed 6 h after 1-h one-legged kicking in young men (from 0.045 to 0.057% hr⁻¹), but is lower than the synthesis rate measured 24 h post-exercise (Miller et al., 2005). Therefore, based on these comparable observations, it can be hypothesized that IGF-I might have a regulatory role on tendon collagen synthesis in response to mechanical loading, but IGF-I is just one of more growth factors, and probably not the major stimulating agent. Another possibility is that the stimulating effect of IGF-I is short-term and only influence the initial rise in tendon collagen synthesis after mechanical loading. That supports the view that it is predominant the last injection of IGF-I in the present study, which led to an increase in tendon collagen synthesis.

In the present study, the injection of IGF-I was placed in the mid-substance of the patella tendon, and ultrasonography assisted the guiding of the needle to ensure placement of the substance. Evidently, it is difficult to document exactly how much the injected volume will spread, but from a recent cadaver study, it is likely that the injected substance will spread proximally and distally along the loose connective tissue between fascicles (Wiegervink et al., 2011). Furthermore, it cannot be excluded that part of the injected IGF-I will disappear via the injection canal. This might have happened as interstitial peritendinous tissue concentration of IGF-I was several (5000–6000×) fold elevated in some of the subjects compared with expected values. It could be hypothesized that in subjects where a greater fraction of the injected dose of IGF-I had disappeared into the peritendinous tissue and circulation, the response in tendon synthesis would be lower compared with other subjects where a greater fraction of the injected dose of IGF-I remained within the tendon. Nevertheless, no correlation between peritendinous IGF-I and tendon collagen FSR was observed to support this notion (n = 11, r = -0.26, P = 0.22). Furthermore, the fact that the circulating level of IGF-I was maintained at a normal level indicates that the two injections of IGF-I into the tendon did not result in any marked disappearance of IGF-I from the tendon region.

**Perspectives**

It may be hypothesized that an additional external stimulation of the fibroblasts by growth factors such as IGF-I may optimize and accelerate tissue healing and shorten time to functional recovery. This is supported by in vitro (Abrahamsson et al., 1991a, b; Abrahamsson & Lohmander, 1996; DesRosiers et al., 1996; Murphy & Nixon, 1997) and animal studies (Kurtz et al., 1999; Dahlgren et al., 2002; Provenzano et al., 2007). Systemic administration of IGF-I after surgical disruption of rat knee medial collateral ligaments has been shown to improve matrix organization, type I collagen expression, type I to type III collagen ratio, and tissue strength with up to ~60% compared with the healing process observed in rats receiving only saline (Provenzano et al., 2007). Similarly, after collagenase-induced degradation, reduced soft tissue swelling, smaller lesion size, and a trend toward improvement of tendon mechanical properties has been observed after 10 local IGF-I injections compared with saline (Dahlgren et al., 2002). To summarize, the present observation of enhanced tendon collagen synthesis after injections of a high local dose of rhIGF-I may indicate that local IGF-I plays an important physiological role in the regulation of collagen-rich tissues. Furthermore, the observation could have implications for connective tissue injury and rehabilitation.
