ABSTRACT

We analysed solar-like oscillations in 1523 *Kepler* red giants which have previously been misclassified as subgiants, with predicted $\nu_{\max}$ values [based on the Kepler Input Catalogue (KIC)] between 280 and 700 μHz . We report the discovery of 626 new oscillating red giants in our sample, in addition to 897 oscillators that were previously characterized by Hekker et al. from one quarter of *Kepler* data. Our sample increases the known number of oscillating low-luminosity red giants by 26 per cent (up to ~ 1900 stars). About three quarters of our sample are classified as ascending red giant branch stars, while the remainder are red-clump stars. A novel scheme was applied to determine $\Delta\nu$ for 108 stars with $\nu_{\max}$ close to the Nyquist frequency ($240 \mu\text{Hz} < \nu_{\max} < 320 \mu\text{Hz}$). Additionally, we identified 47 stars oscillating in the super-Nyquist frequency regime, up to 387 μHz , using long-cadence light curves. We show that the misclassifications are most likely due to large uncertainties in KIC surface gravities, and do not result from the absence of broad-band colours or from different physical properties such as reddening, spatial distribution, mass or metallicity. The sample will be valuable to study oscillations in low-luminosity red giants and to characterize planet candidates around those stars.

Key words: techniques: photometric – stars: oscillations.

1 INTRODUCTION

The advent of space-borne missions such as *WIRE* (Buzasi et al. 2000), *MOST* (Walker et al. 2003), *SMEI* (Tarrant et al. 2007), *CoRoT* (Michel et al. 2008) and *Kepler* (Gilliland et al. 2010) have revolutionized the study of oscillations driven by turbulent near-surface convection (so-called solar-like oscillations, Chaplin & Miglio 2013). Solar-like oscillations exhibit radial and non-radial modes excited over multiple overtones, with amplitudes roughly following a Gaussian distribution. The long, continuous and high-quality light curves from *Kepler* provide seismic parameters such as the frequency of maximum oscillation power ($\nu_{\max}$) and the mean large frequency separation ($\Delta\nu$). Those can be used in combination with scaling relations to derive stellar properties such as masses, radii, densities and even ages, provided complementary spectroscopic and/or photometric information is available (Stello et al. 2009; Kallinger et al. 2010). Additionally, asteroseismology has al-

lowed new insights into the interior structure, rotation and magnetic fields of red giants (Bedding et al. 2011; Beck et al. 2012; Mosser et al. 2012c; Fuller et al. 2015; Stello et al. 2016b).

So far, seismic parameters have been determined for some 500 main-sequence and subgiant stars (Chaplin et al. 2011, 2014a) and for over 15 000 red giants (Huber et al. 2010, 2011; Hekker et al. 2011; Mosser et al. 2012a; Stello et al. 2013), most of which had previously been identified as red giants in the Kepler Input Catalogue (KIC, Brown et al. 2011). Huber et al. (2014) identified 2762 new oscillating red giants which were previously unclassified in the KIC and consolidated stellar characterizations of 196 468 targets observed by the *Kepler* Mission.

In this paper, we are motivated by the fact that some red giants might be misclassified as subgiants in the KIC. While the KIC was successful in its primary goal to distinguish dwarfs from giants, some studies have indicated that KIC stellar parameters are significantly biased for subgiants (Molenda-Zakowicz et al. 2011; Verner et al. 2011; Thygesen et al. 2012; Mathur et al. 2016). The second motivation stemmed from recent work by Chaplin et al. (2014b), who found that oscillation frequencies located as high as $\sim 500 \mu\text{Hz}$ can be detected with long-cadence (29.4 min) data, for

* E-mail: jiyu9229@uni.sydney.edu.au (JY); dhuber@physics.usyd.edu.au (DH); T.Bedding@physics.usyd.edu.au (TRB)

which the Nyquist frequency is 283.2 μHz . This followed on from work by Murphy, Shibahashi & Kurtz (2013), who argued that *Kepler*'s Nyquist aliases are split into multiplets which allow us to discriminate real oscillations from the aliased counterpart. Hence, additional asteroseismic red giants may be identified in the super-Nyquist regime.

2 SAMPLE SELECTION

We selected 4758 candidates with KIC effective temperatures less than 6000 K and KIC-predicted ν_{max} ranging from near the Nyquist frequency (280 μHz) to 700 μHz . The predicted ν_{max} values were calculated using the scaling relation (Brown et al. 1991):

$$\frac{\nu_{\text{max}}}{\nu_{\text{max},\odot}} \simeq \frac{g/g_{\odot}}{\sqrt{(T_{\text{eff}}/T_{\text{eff},\odot})}}. \quad (1)$$

We used KIC surface gravities (Brown et al. 2011) and adopted solar values $\nu_{\text{max},\odot} = 3050 \mu\text{Hz}$, $g_{\odot} = 27\,487 \text{ cm s}^{-2}$ and $T_{\text{eff},\odot} = 5777 \text{ K}$. We omitted targets with predicted ν_{max} larger than 700 μHz due to the low expected rate of seismic detections, given that those stars are possibly dwarfs or subgiants based on their effective temperatures.

3 DATA ANALYSIS

3.1 Full sample

We have searched all candidates for solar-like oscillations using long-cadence data (Jenkins et al. 2010) obtained during the full *Kepler* Mission (Q0–Q17). We used simple aperture photometry for our analysis.

Raw light curves were prepared following the procedure described by García et al. (2011). The safe modes have been cut out and instrumental flux discontinuities were corrected using a linear fit. In order to remove signals due to low-frequency stellar activity and instrumental artefacts, we applied a quadratic Savitzky–Golay filter with a length of 10 d. We calculated the power spectrum for each target and checked them by eye for the presence of oscillations. Finally, we used the SYD pipeline (Huber et al. 2009) to extract the global oscillation parameters, including ν_{max} , $\Delta\nu$ and amplitude at ν_{max} , and calculated the corresponding uncertainties using the same scheme as Huber et al. (2011).

We followed the original method to measure ν_{max} below the Nyquist frequency. To determine ν_{max} above the Nyquist frequency, we refitted the background rather than simply using the reflected background, considering the aliased power spectrum as a superposition of the reflected power and real power in the super-Nyquist regime. We tested this method by selecting stars for which both long-cadence and short-cadence data are available, and found good agreement (to within ~ 1 per cent) in the seismic parameters from the two data sets.

Considering that the predicted ν_{max} values for the targets in our sample are above the Nyquist frequency, it is important to be able to distinguish the real power excess from its aliased counterpart. Indeed, one of our aims is to explore the seismic oscillations in the super-Nyquist frequency region using the long-cadence data (Chaplin et al. 2014a). Therefore, we applied the following approach to identify the real oscillations in the power spectrum. In its original form, the Huber et al. (2009) pipeline calculated the autocorrelation function (ACF) below the Nyquist frequency and determined $\Delta\nu$ from whichever of the 10 highest peaks of the ACF was closest to the predicted $\Delta\nu$ using scaling relation. In this work, we computed the power spectrum for each target to twice the Nyquist frequency,

heavily smoothed the ACF of this power spectrum, selected the frequencies of the two highest peaks, τ_1 and τ_2 , and assigned $(2/3)(\tau_1 + \tau_2)$ as the predicted $\Delta\nu$. We multiplied by the factor 2/3 because τ_1 and τ_2 correspond to $\Delta\nu$ and half $\Delta\nu$, respectively. Note that this method does not apply to the oscillating stars with suppressed dipole modes, in which case, we just selected the highest peak and assigned its frequency, τ , to the predicted $\Delta\nu$. Dipole-mode suppressed oscillators were identified using visual inspection. The resulting $\Delta\nu$ is then determined by whichever of the 10 highest peaks of ACF was closest to the predicted $\Delta\nu$. The scheme was applied to both sides of the Nyquist frequency separately. Realizing the fact that the frequencies of maximum seismic power are distinct, appearing reflected about the Nyquist frequency, we then distinguished the real from the aliased power excess by comparing which set of ν_{max} and $\Delta\nu$ agrees better with the relation

$$\Delta\nu \simeq \alpha(\nu_{\text{max}}/\mu\text{Hz})^\beta, \quad (2)$$

where $\alpha = 0.268 \mu\text{Hz}$, $\beta = 0.758$ (Huber et al. 2010).

Fig. 1 shows representative power spectra up to twice the Nyquist frequency for five of our detected oscillating giants with high-signal-to-noise (S/N) ratios, including the real (red-shaded region between solid lines) and aliased (grey-shaded region between dashed lines) power excesses. The blue-dashed line marks the Nyquist frequency. Each target is labelled by the KIC number, predicted ν_{max} based on KIC stellar parameters, and our measured ν_{max} and $\Delta\nu$. Note that the KIC-predicted ν_{max} deviates significantly from the observed values. The five stars have monotonically increasing ν_{max} , with KIC 12118322 being the most evolved star ($\nu_{\text{max}} = 66.8 \mu\text{Hz}$), while KIC 9894103 and KIC 11081207 oscillate above the Nyquist frequency.

We can see that the maximum amplitudes decrease and the widths of the oscillation envelope increase with increasing ν_{max} (Huber et al. 2011). It is known that for each pair of adjacent $l = 2$ (quadrupole) and $l = 0$ (radial) modes, the latter has the greater power and resides at higher frequency. The asymmetry helps confirm the correct identification. This can be seen clearly in KIC 9511816, KIC 9894106 and KIC 11081207 due to their larger $\Delta\nu$. For the aliased envelopes, the power of the radial mode is lower than the quadrupole mode within each pair, contrary to expectations.

We note that for KIC 12118322, KIC 6060703 and KIC 9511816, the amplitudes of the real excess in Fig. 1 appear to be lower than those of the aliased excess, which is contrary to the results given by Murphy et al. (2013). We found that the application of a high-pass filter and background removal leads to these reduced amplitudes. However, this difference has negligible influence on the remainder of our analysis.

3.2 Stars oscillating near the Nyquist frequency

The method described in Section 3.1 does not work well for stars oscillating close to the Nyquist frequency, given parameters uncertainties and, in particular, the difficulty in determining ν_{max} . Hence, we applied a different method for those stars.

It is known that high-order acoustic modes follow the asymptotic relation, $\nu \approx \Delta\nu(n + l/2 + \epsilon)$, where ϵ may be evaluated from $\Delta\nu$ based on the relation: $\epsilon = 0.634 + 0.63\log(\Delta\nu)$ (Corsaro et al. 2012). The large separation $\Delta\nu$ returned from the pipeline can therefore be used to predict ϵ since it is measured independently of ν_{max} (Section 3.1).

To select the power spectrum regions dominated by $l = 0$ and $l = 2$, we employed the relation: $-0.22 < (\nu/\Delta\nu - \epsilon) \bmod 1 < -0.06$ for $l = 2$ and $-0.06 < (\nu/\Delta\nu - \epsilon) \bmod 1 < 0.10$ for $l = 0$

Figure 1. Power spectra of five representative red giants. The blue-dashed line denotes the Nyquist frequency (283.22 μHz). The red-shaded region between solid lines represents the real oscillation power excess, while grey-shaded area between dashed lines shows its aliased counterpart. Each star is labelled by KIC number, predicted $\nu_{\max}$ [using equation (1) in combination with KIC effective temperature and surface gravity], observed $\nu_{\max}$ and $\Delta\nu$.

(Stello et al. 2016b,a). We selected up to four pairs of radial and quadrupole modes which were closest to the highest peak at both sides of the Nyquist frequency. We did this instead of using $\nu_{\max}$ from the pipeline since $\nu_{\max}$ is less accurate for stars oscillating near the Nyquist frequency. Both the real and aliased excesses were matched against a fine structure template constructed via the $\epsilon - \Delta\nu$ relation and the one with the higher agreement with the template was selected as the real excess. However, this scheme does not work well if the real mode pattern falls symmetrically around the Nyquist frequency (i.e. either if an acoustic dipole resonance mode or a pair of $l = 0, 2$ modes fall right at the Nyquist frequency). In such case, we compared the power of radial modes with that of quadrupole modes on either side of the Nyquist frequency. We identify the real excess as that where the modes identified as quadrupoles are of lower power than their neighbouring radial modes. In practice, we performed this only if $|p_1 - p_2|/p_1 < 20$ per cent, where p_1 and p_2 represent the total power dominated by radial and quadrupole modes below and above the Nyquist frequency, respectively. We selected a slightly conservative threshold (20 per cent), given that the relations for predicting the $l = 0$ and $l = 2$ dominated frequency regions are not exact.

Fig. 2 displays four representative stars with $\nu_{\max}$ close to the Nyquist frequency. The power spectra have been smoothed to a resolution of 0.5 μHz . Red indicates the regions identified as ra-

dial modes from the $\epsilon - \Delta\nu$ relation while blue shows quadrupole modes. The real power excess determined by the scheme agrees well with the result from the pipeline for a star oscillating below the Nyquist frequency, as shown in Fig. 2(a), and a star oscillating in the super-Nyquist region, as shown in Fig. 2(b), and confirms the seismic parameters, in particular $\Delta\nu$. Conversely, $\nu_{\max}$ for the star in panel (c) was overestimated ($\nu_{\max}$ returned from the pipeline was 311.6 μHz), while in panel (d) it was underestimated ($\nu_{\max}$ returned from the pipeline was 256.8 μHz). The accuracy of $\Delta\nu$ from the pipeline is confirmed after realizing the excellent agreement between the identified and real modes. We applied the scheme to 108 stars with $\nu_{\max}$ from 240 to 320 μHz and confirmed the accuracy of $\Delta\nu$ by eye.

4 RESULTS

In this section, we present our main results for the entire sample and compare our detections to the sample of Huber et al. (2011). Our sample consists of 1523 stars, all of which have oscillations that are clearly visible in the power spectra. After excluding outliers and some targets which have been previously analysed, we report the discovery of 626 new oscillating red giants. The majority of known red giants were investigated by Hekker et al. (2011), who analysed solar-like oscillations in those red giants by using only one quarter

Figure 2. Identification of the real power excess for four representative stars oscillating near the Nyquist frequency. The power spectra have been smoothed with a boxcar filter with a width of $0.5 \mu\text{Hz}$ and the background has been subtracted. Red indicates the regions identified by radial modes while blue shows quadrupole modes. Each target is labelled by its KIC ID, observed ν_{max} (if correctly measured from the pipeline), $\Delta\nu$ and real power excess (L stands for power excess below the Nyquist frequency while R stands for power excess above the Nyquist frequency).

Table 1. Global oscillation parameters: ν_{max} , $\Delta\nu$ and amplitude.

KIC ID	ν_{max} (μHz)	$\Delta\nu$ (μHz)	Amplitude (ppm)

Note. Asterisks indicates that the corresponding values are not available due to the ν_{max} being close to the Nyquist frequency (between $240 \mu\text{Hz}$ and $320 \mu\text{Hz}$). Values in brackets represent uncertainties.

(This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.)

of *Kepler* data. The application of data from full *Kepler* Mission in our work enables us to measure seismic parameters more precisely. We list global seismic parameters, ν_{max} , $\Delta\nu$ and the amplitude per radial mode (Kjeldsen et al. 2008; Huber et al. 2010) in Table 1.

Note that ν_{max} values for stars between 240 and $320 \mu\text{Hz}$ were omitted because of the difficulty of precisely measuring ν_{max} near the Nyquist frequency.

4.1 Global asteroseismic parameters: ν_{max} , $\Delta\nu$ and Amplitude

Fig. 3 illustrates the global asteroseismic parameters, ν_{max} and $\Delta\nu$ for the whole sample (red squares) and compared with the sample of Huber et al. (2011, grey circles). ν_{max} and $\Delta\nu$ follow the well-known power-law relation as given in equation (2). The fitted coefficients, $\alpha = 0.262 \pm 0.001$ and $\beta = 0.770 \pm 0.001$, are consistent with Huber et al. (2011) and almost identical to the original fit by Stello et al. (2009). Uncertainties were calculated using a Monte Carlo simulation and are smaller than in the literature due to the longer data sets used in our work.

To reveal the additional information encoded in ν_{max} and $\Delta\nu$, we took a ratio of ν_{max} and $\Delta\nu$ which is solely dependent on mass and temperature (Huber et al. 2011):

$$\frac{(\nu_{\text{max}}/\mu\text{Hz})^{0.75}}{\Delta\nu/\mu\text{Hz}} \propto \left(\frac{M}{M_{\odot}}\right)^{0.25} \left(\frac{T_{\text{eff}}}{T_{\text{eff},\odot}}\right)^{-0.375} \quad (3)$$

The result is shown in Fig. 3(b), where asteroseismic masses, which were calculated from ν_{max} , $\Delta\nu$ and the KIC effective temperature, are colour coded. We can see clearly that the diversity of masses

Figure 3. (a): $\Delta\nu$ versus $\nu_{\max}$ for the entire sample (red squares) and those from Huber et al. (2011, grey circles). (b): $\nu_{\max}^{0.75}/\Delta\nu$ versus $\nu_{\max}$. The blue-dashed line denotes the Nyquist frequency (283.22 μHz). Asteroseismic masses are colour coded, which were derived by combining $\nu_{\max}$, $\Delta\nu$ and KIC effective temperature. We can see clearly the diversity of masses dominates the scatter in the vertical direction. Note that we excluded the stars with measured $\nu_{\max}$ in the range of 240 and 320 μHz (see text).

of red giants produces the scatter in the vertical direction. We have checked that the effect of effective temperature on the distribution is minor, reflecting the fact that red giants, in particular in our sample, have similar effective temperatures. The agreement between our sample and those from Huber et al. (2011) is good. Note that the red-clump stars, which are in the helium-core burning phase, produce increased number of stars seen in both panels at $\nu_{\max}$ around 20–50 μHz because of the relatively longer evolutionary lifetime.

Huber et al. (2011) also tested the scaling relation for oscillation amplitudes from the main sequence to red giants. They made a comparison between the observed and predicted amplitudes, which were based on the scaling relation:

$$A_{Kp} \propto \frac{L^s}{M^t T_{\text{eff}}^{r-1} C_K(T_{\text{eff}})}, \quad (4)$$

where L is the luminosity, M is the mass, T_{eff} is the effective temperature, $s = 0.838 \pm 0.002$ and $t = 1.32 \pm 0.02$ are the fitted coefficients, r is fixed at 2 (Huber et al. 2011), and $C_K(T_{\text{eff}})$ is the bolometric correction factor (Ballot, Barban & van't Veer-Menneret 2011),

$$C_K(T_{\text{eff}}) = \left(\frac{T_{\text{eff}}}{5934 \text{ K}} \right)^{0.8}. \quad (5)$$

Huber et al. (2011) argued that the spread of amplitudes, which is significantly larger than the uncertainties at a given $\nu_{\max}$, is partially due to the dispersion of stellar masses and that lower mass stars show larger amplitudes at a given $\nu_{\max}$. In Fig. 4, we do see the amplitude dispersion and the mass–amplitude relation, both of which have good agreement with those from Huber et al. (2011). We have checked the outliers at $\nu_{\max} \sim 37.0 \mu\text{Hz}$ and found the corresponding amplitude is reliable, indicating that the low amplitude may arise from an unresolved companion that dilutes the oscillation amplitude. We can also see a few stars which have relatively lower amplitudes near the Nyquist frequency. Manual inspection showed

Figure 4. Oscillation amplitude at $\nu_{\max}$ against $\nu_{\max}$ for the whole sample (colour coded by the seismic mass). Targets from Huber et al. (2011) are plotted as grey circles. The blue-dashed line denotes the Nyquist frequency (283.22 μHz). Targets oscillating near the Nyquist frequency have underestimated amplitudes (see text).

that this is due to the difficulty of determining the photon noise level when the frequency of maximum oscillation power is close to the Nyquist frequency.

4.2 Evolutionary states

It is well known that the red giants in the hydrogen-shell-burning phase [red giant branch (RGB)] and giants in the helium-core burning phase, which are designated as red-clump stars (RC1) and secondary red-clump stars (RC2), overlap in the Hertzsprung–Russell diagram (H–R diagram), making them difficult to discern using classical observing techniques. Bedding et al. (2011) and Mosser et al. (2012b) proposed that period spacings of mixed dipole modes can be used to disentangle the RGB (period spacings of ~ 50 s) from RC1 and RC2 (period spacings between 100 and 300 s). Stello et al. (2013) extended this investigation to classify stellar populations amongst 13 000 red giants. Recently, Mosser et al. (2015) and Vrad, Mosser & Samadi (2016) have utilized new methods to measure rotational splittings and period spacings in an automatic way. Takeda, Sato & Murata (2008) and Takeda & Tajitsu (2015) adopted an alternative approach by distinguishing the evolutionary states in a surface gravity against mass diagram. Since measuring period spacings is beyond the scope of this paper, we apply the log g –mass method to explore evolutionary states.

First, as seen in Figs 3 and 4, targets in our sample are mainly red giants, which generally have $\nu_{\max}$ less than 300 μHz . Fig. 5(a) shows the asteroseismic H–R diagram with each target from our sample colour coded by oscillation amplitude. Compared with the sample from Huber et al. (2011), our sample lacks more evolved red giants with $\nu_{\max}$ less than 20 μHz , which results from our low-frequency threshold of 10 μHz and from the fact that the KIC classifications are more accurate for cool stars. Again, the gap seen in panel (a) is due to the absence of $\nu_{\max}$ measurements in the range 240–320 μHz . This gap is filled substantially if instead of $\nu_{\max}$, we plot $\Delta\nu$ as shown in panel (b), where newly discovered oscillating red giants are indicated by cyan open triangles.

To further classify different populations in our sample, we plotted the asteroseismic surface gravities versus masses in Fig. 6 with approximate evolutionary stages. RGB stars account for ~ 71 per cent of sample while RC1 stars take up ~ 25 per cent of sample. The

Figure 5. (a): $\nu_{\max}$ versus T_{eff} diagram. The abscissa is the KIC effective temperature. Targets from the entire sample are colour coded by their amplitudes. Stars from Huber et al. (2011) are shown as grey circles for comparison. The gap is due to the absence of $\nu_{\max}$ measurements in the range 240 μHz to 320 μHz . (b): $\Delta\nu$ versus T_{eff} diagram. Newly discovered oscillating red giants are shown as cyan open triangles. Stars with $\nu_{\max}$ near the Nyquist frequency are denoted as blue squares.

Figure 6. Asteroseismic surface gravities versus masses. Targets are colour coded by the oscillation amplitude. Boxes label approximate evolutionary stages for RGB and RC2. Stars outside the boxes are RC1.

remaining ≈ 4.0 per cent of stars have seismic masses larger than $2.0 M_{\odot}$ and can either be classified as RGB or RC2 (statistically more likely to be RC2 stars). The higher amplitude stars with surface gravities from 2.5 to 2.8 dex and seismic masses from 1.1 to $1.4 M_{\odot}$ (green points) are likely higher luminosity RGB stars or asymptotic giant stars. RC1 stars are also well classified with a bar shape at the left-bottom corner, which show the highest amplitudes as colour coded by the green and red squares. The RGB stars mostly consist of low-luminosity red giants which have relative low oscillation amplitude as denoted by the blue points.

Figure 7. Histograms of $\Delta\nu$ and $\nu_{\max}$. Red curve represents our sample while black curve indicates Huber et al. (2011) and Stello et al. (2013) samples. The blue-dashed lines mark the Nyquist frequency in panel (b) and its corresponding $\Delta\nu$ calculated from scaling relation in panel (a). The short-cadence sample by Huber et al. (2011) is not shown here.

Compared to Huber et al. (2011) and Stello et al. (2013) samples, our sample increases the number of low-luminosity ($\nu_{\max} > 100 \mu\text{Hz}$) red giants by ~ 26 per cent (up to ~ 1900 stars). Fig. 7 illustrates the histograms of $\nu_{\max}$ and $\Delta\nu$ for our sample (red curve) as well as the combined Huber et al. (2011) and Stello et al. (2013) samples (black curve). Panel (a) shows all the targets in our sample, including stars oscillating near the Nyquist frequency, while panel

Figure 8. KIC-predicted versus observed $\nu_{\max}$ for the entire sample (red squares) and those of Huber et al. (2011, grey circles). KIC-predicted $\nu_{\max}$ values were derived from equation (1) with KIC temperatures and surface gravities. The green-dashed line denotes the 1:1 relation, while the blue-dashed line represents the lower limit of the predicted $\nu_{\max}$ for the sample selection.

(b) does not display those stars. We can see from panel (b) that our sample has a large number of low-luminosity red giants. It also includes 47 stars oscillating beyond the Nyquist frequency, up to 387 μHz .

Low-luminosity red giants are characterized by broad power excess and rich modes due to the presence of mixed modes and rotational splittings. An expanded sample of low-luminosity red giants is therefore very valuable to asteroseismically understand their global properties and internal structures. We find 16 stars in our sample are planet-candidate host stars which harbour 17 exoplanet candidates listed in the NASA Exoplanet Archive.¹ Those exoplanet candidates will be investigated in a follow-up paper.

5 DISCUSSION

As shown in Section 4, our sample is mostly comprised of low-luminosity red giants and red-clump stars, suggesting that the predicted $\nu_{\max}$ values based on the KIC are significantly biased compared with the observed $\nu_{\max}$. Fig. 8 shows that the KIC and observed $\nu_{\max}$ values for our sample strongly deviate from the one-to-one relation, while the targets in Huber et al. (2011) show better agreement. In order to understand the cause of the offset in $\nu_{\max}$ shown in Fig. 8, we used spectroscopic data to determine whether this offset originates from some particular physical properties in our sample or from random errors.

5.1 Comparison with LAMOST

The LAMOST (Large Sky Area Multi-Object Fiber Spectroscopic Telescope; Zhao et al. 2012) survey collected low-resolution ($R \approx 1800$) optical spectra (3800–9000 Å) for objects in the *Kepler* fields (Cui et al. 2012; De Cat et al. 2015; Luo et al. 2015). Stellar atmospheric parameters (T_{eff} , $\log g$, [Fe/H]) of the LAMOST-*Kepler* spectra collected before 2014 September were derived with LSP3 pipeline (Xiang et al. 2015). The LSP3 pipeline uses template

Figure 9. Comparison of effective temperature from KIC and LAMOST for our sample (red squares) and those of Huber et al. (2011, grey circles). The green-dashed line shows the 1:1 relation in panel (a) and the mean difference in the sense of KIC minus LAMOST in panel (b) for our sample.

matching with the MILES stellar spectra library, and estimates measurement uncertainties of stellar atmospheric parameters for individual stars based on their S/N and location in the stellar parameter space. Detailed tests have shown that LSP3 provides parameters with an overall accuracy of about 150 K (T_{eff}), 0.25 dex ($\log g$) and 0.15 dex ([Fe/H]), given a spectral S/N ratio higher than 10 (Xiang et al. 2015). For F/G-type stars with high spectral S/N, uncertainties can be even smaller than 100 K (T_{eff}), 0.2 dex ($\log g$) and 0.1 dex ([Fe/H]).

There are 368 common stars between our sample and the LAMOST-*Kepler* catalogue (Xiang et al. 2015). We first compared KIC with LAMOST effective temperatures as shown in Fig. 9. Panel (a) indicates that there is a good agreement between the two temperature scales, with the KIC temperatures being slightly hotter. After removing eight outliers using 4σ clipping, we obtained the mean and scatter of the residuals in our sample (in the sense of KIC minus LAMOST) as $+47 \text{ K} \pm 154 \text{ K}$. Inspection of Fig. 9 also reveals a similar offset and spread arising for the red giants from the Huber et al. (2011) sample. For main-sequence stars, spectroscopic temperatures from LAMOST are higher, consistent with previous comparisons (Pinsonneault et al. 2012; Huber et al. 2014).

In addition to the effective temperature, surface gravity is the other source of uncertainty for predicting $\nu_{\max}$. Asteroseismology provides accurate $\log g$ measurements and hence has been used as input to lift the degeneracy between spectroscopic temperature, surface gravity and metallicity (Bruntt et al. 2012; Huber et al. 2013; Pinsonneault et al. 2014; Liu et al. 2015).

Fig. 10 compares the asteroseismic and LAMOST surface gravities against those from the KIC. Panel (a) clearly illustrates the misclassification of targets in our sample, where KIC surface gravities are greater than 3.4 dex and hence classified as subgiants while the seismic values are less than 3.5 dex and thus are classified as red giants (see Figs 3–6).

In panel (b), we observe a similar distribution as shown in panel (a) but with larger scatter, which confirms the misclassification of our sample as subgiants by the KIC. With respect to targets from

¹ <http://exoplanetarchive.ipac.caltech.edu/index.html>

Figure 10. (a) Asteroseismic versus KIC surface gravities for the entire sample (red squares) and those of Huber et al. (2011, grey circles). Asteroseismic surface gravities are derived using equation (1) in combination with observed $\nu_{\max}$ and KIC effective temperature. (b): Same with panel (a) but for LAMOST. Typical uncertainties are shown for each surface-gravity scales in both panels.

Huber et al. (2011), the agreement in both panels is good overall but still has substantial spread, in particular for dwarfs in panel (b). The mean and scatter of the $\log g$ residuals are -0.10 ± 0.30 dex in the sense of seismic minus KIC and -0.15 ± 0.35 dex in the sense of LAMOST minus KIC. We are therefore able to conclude that the incorrect determination of KIC surface gravities for our sample is the main cause for the erroneous prediction of $\nu_{\max}$.

5.2 Are the red giants in our sample physically different?

Realizing that incorrect KIC surface gravities are responsible for the incorrect $\nu_{\max}$ predictions makes us wonder whether some particular physical properties led to the misclassification of our sample in the KIC. To explore whether our sample and the Huber et al. (2011) sample are physically different in metallicity, we illustrate the corresponding comparison in Fig. 11. It shows that the two samples are similar in metallicity, spanning from -1.4 dex to 0.5 dex. Comparing with LAMOST, KIC metallicities of both samples were underestimated in the metal-poor regime but overestimated in the metal-rich region. In panel (b), we clearly observe this trend with a mean and standard deviation of -0.061 and 0.210 dex, respectively, in the sense of KIC minus LAMOST. This is consistent with the metallicity trend found by Dong et al. (2014).

We also checked if the lack of seven independent colours (derived from eight filters: KIC *griz*, D51 and 2MASS *JHK*) contributes to the incorrect KIC-predicted $\nu_{\max}$ values. However, only three stars do not have a full set of colours and therefore we excluded this effect as a dominant cause for the larger errors in $\log g$.

In Fig. 12, we compare *Kepler* magnitudes, KIC reddening, asteroseismic masses and spatial distribution for our sample (red data) with the samples from Huber et al. (2011, grey data) and Stello et al. (2013, blue data). Note that we have restricted both compari-

Figure 11. Same with Fig. 9 but for metallicity.

son samples to seismic gravities in the same ranges as our sample (from 2.2 to 3.5 dex).

From Fig. 12(a), we can see, due to the preferential selection of bright stars by the Kepler Asteroseismic Science Consortium, our sample is systematically fainter by nearly 2 mag, compared to Huber et al. (2011). We note that Huber et al. (2011) used data spanning from Q0 to Q6 for long-cadence light curves and Q0 to Q4 for short-cadence light curves, whereas we used data from the entire nominal *Kepler* Mission (Q0–Q17). Longer time series enhance the probability of detecting oscillations in fainter stars. Both our sample and the Stello et al. (2013) sample show a sharp cut at $K_p = 14$ mag due to the *Kepler* selection function (Batalha et al. 2010). Panel (b) shows most targets in our sample have reddening around 0.13 mag, which is consistent with the sample of Huber et al. (2011) but shifted by 0.03 mag compared to the Stello et al. (2013) sample. Inspection of panel (b) also reveals there are a population of stars with lower reddening peaking at 0.035 mag. To understand if this population of stars reside in special location, we plotted the spatial distribution of targets for our sample (red dots) and Stello et al. (2013, blue dots) in the entire *Kepler* field of view. We see fewer targets located in the three modules at the bottom-right corner, which are closest to the Galactic plane and have less stars because of the *Kepler* targets selection function. Particularly, we checked that the population of stars with reddening less than 0.08 are almost uniformly distributed. Thus, we can conclude that sky position does not correlate with the incorrect KIC surface gravities.

It is tempting to speculate that the ≈ 0.03 mag systematic reddening shift between our sample and the Stello et al. (2013) sample might be responsible for the wrong determination of surface gravities and hence lead to the incorrect KIC $\nu_{\max}$ prediction. However, we should note that KIC effective temperatures show good agreement with the LAMOST values. Besides, it is also possible that the larger reddening values are a simple consequence of the fact that the Stello et al. (2013) sample includes more evolved stars, which are on average more distant, keeping in mind the similar magnitude distributions for our sample and Stello et al. (2013).

In panel (d), we plot the histogram of seismic masses and find that stars for all three samples have asteroseismic masses peaking

Figure 12. Histograms for *Kepler* magnitude K_p [panel (a)] and KIC reddening [panel (b)], spatial distribution in *Kepler* field of view [panel (c)] and histogram of asteroseismic mass [panel (d)]. The red data represents targets of our entire sample, the grey data indicates those from Huber et al. (2011) while the blue data are targets from Stello et al. (2013).

around $1.2 M_{\odot}$, although stars from Huber et al. (2011) have a slightly wider spread.

Therefore, we can conclude from Figs 11 and 12 that targets from this work and the previous studies are similar in terms of reddening, sky position, mass and metallicity. This indicates that our sample is not physically different compared to the Huber et al. (2011) and Stello et al. (2013) samples, and that the misclassification is most likely due to random errors in the KIC surface gravity values.

6 CONCLUSIONS

We selected 4758 stars with KIC-predicted $\nu_{\max}$ ranging from close to the Nyquist frequency (280 μHz) to 700 μHz . Based on the SYD pipeline applied to the long-cadence light curves observed by *Kepler*, we detected unambiguous oscillations in 1523 red giants and reported the discovery of 626 new oscillating red giants. Our sample increases the known number of oscillating low-luminosity red giants by 26 per cent (up to ~ 1900 stars) and includes 47 seismic targets residing in the super-Nyquist frequency region up to 387 μHz . RGB stars account for approximately 70.5 per cent of the sample while RC1 stars take up ~ 24.5 per cent of sample. The remaining ~ 5.0 per cent of stars can either be classified as RGB or RC2, but further discrimination needs more detailed analysis.

The significant difference between the observed and KIC-predicted $\nu_{\max}$ arises mostly from the incorrect determination of surface gravities. Comparison of asteroseismic surface gravities with those from the KIC clearly illustrates the misclassification

of targets in our sample. Surface gravities returned from the KIC are greater than 3.4 dex for all stars while seismic values are less than 3.5 dex, thus classifying those stars as red giants.

We argue that the incorrect KIC surface gravities do not result from the physical properties such as reddening, spatial distribution, mass or metallicity between our sample and those from Huber et al. (2011) and Stello et al. (2013). We hence believe that our sample is not physically different compared to the one of Huber et al. (2011), but rather a result of misclassification due to large errors in the KIC.

The unambiguous oscillations are very valuable to understand stellar global properties and interior structure such as rotation and magnetic fields. The key synergies between asteroseismology and exoplanet science will also allow us to characterize planet candidates around those stars provided transit and oscillations can be detected simultaneously (Yu et al. in preparation). We are also in the process of compiling a full catalogue of asteroseismic parameters for all oscillating red giants observed over the 4-yr *Kepler* Mission.

ACKNOWLEDGEMENTS

The authors would like to thank the referee for a careful reading of our manuscript and many helpful comments. We gratefully acknowledge the entire *Kepler* team and everyone involved in the *Kepler* mission for making this paper possible. Funding for the *Kepler* Mission is provided by NASA's Science Mission Directorate. Some/all of the data presented in this paper were obtained from the

Mikulski Archive for Space Telescopes (MAST). STScI is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5-26555. Support for MAST for non-*Hubble Space Telescope* data is provided by the NASA Office of Space Science via grant NNX09AF08G and by other grants and contracts. Guoshoujing Telescope (the Large Sky Area Multi-Object Fiber Spectroscopic Telescope, LAMOST) is a National Major Scientific Project which is built by the Chinese Academy of Sciences, funded by the National Development and Reform Commission, and operated and managed by the National Astronomical Observatories, Chinese Academy of Sciences. DH acknowledges support by the Australian Research Council's Discovery Projects funding scheme (project number DE140101364) and support by the National Aeronautics and Space Administration under Grant NNX14AB92G issued through the Kepler Participating Scientist Programme. TDL acknowledges support by grant 11273007 from the National Natural Science Foundation of China.
