CREATES Research Paper 2009-26

Tails, Fears and Risk Premia

Tim Bollerslev and Viktor Todorov
Abstract

We show that the compensation for rare events accounts for a large fraction of the equity and variance risk premia in the S&P 500 market index. The probability of rare events vary significantly over time, increasing in periods of high market volatility, but the risk premium for tail events cannot solely be explained by the level of the volatility. Our empirical investigations are essentially model-free. We estimate the expected values of the tails under the statistical probability measure from “medium” size jumps in high-frequency intraday prices and an extreme value theory approximation for the corresponding jump tail density. Our estimates for the risk-neutral expectations are based on short maturity out-of-the money options and new model-free option implied variation measures explicitly designed to separate the tail probabilities. At a general level, our results suggest that any satisfactory equilibrium based asset pricing model must be able to generate large and time-varying compensations for fears of disasters.

Keywords: rare events, jumps, high-frequency data, options, fears, extreme value theory, equity risk premium, variance risk premium.

JEL classification: C13, C14, G10, G12.
1 Introduction

“So what are policymakers to do? First and foremost, reduce uncertainty. Do so by removing tail risks, and the perception of tail risks.”

Olivier Blanchard, chief economist, IMF, The Economist, January 31, 2009

The lack of investor confidence is frequently singled out as one of the main culprits behind the massive losses in market values in the advent of the Fall 2008 financial crises. At the same time, the portrayal in the financial news media of different doomsday scenarios in which the stock market would decline even further have become increasingly more commonplace. Motivated by these observations, we provide a new theoretical framework for better understanding the way in which the market prices and perceives tail risks. Our estimates rely on the use of actual high-frequency intraday data and short maturity out-of-the-money options. Our empirical results based on data for the S&P 500 index spanning the period from 1990 until mid-2007 show that the market generally incorporates the possible occurrence of rare disasters in the way in which it prices risky payoffs, and that the fear of such events accounts for a surprisingly large fraction of the historically observed equity and variance risk premia. Extending our results through the end of 2008 we document an even larger role of investor fears during the recent financial market crises. As such, our findings support the above conjecture that removing the perception of tail risk should help restore asset values.

The idea that rare disasters, or tail events, may help explain the equity premium and other empirical puzzles in asset pricing finance dates back at least to Rietz (1988). While the original work by Rietz (1988) was based on a peso type explanation and probabilities of severe events that exceed those materialized in sample, more recent work by Barro (2006) and Barro and Ursua (2008) have argued that when calibrated to international data, actual disaster events do appear frequent enough to meaningfully impact the size of the equity premium. Further building on these ideas, Gabaix (2008) and Wachter (2008) have recently shown that explicitly incorporating time-varying risks of rare disasters in otherwise standard equilibrium based asset pricing models may help explain both the equity premium and the apparent excess volatility of aggregate market returns.1

In contrast to these studies, which extrapolate the impact of rare disasters from equilibrium based pricing models and auxiliary assumptions about the likelihood of disasters, we rely on actual sample realizations from U.S. futures and options markets and new statistical tools to back out the objective expectations of tail events and the market’s pricing thereof. In particular, building on new extreme value theory in Bollerslev and Todorov (2009), we use the relatively frequent “medium” size jumps in high-frequency intraday returns in the construction of reliable estimates for the expected interdaily tail events under the statistical probability measure, thereby explicitly avoiding peso type explanations. Similarly, our estimates for the market risk-neutral expectations are based on actual short maturity out-of-the

---

1In a related context, Bianchi (2008) shows how incorporating agents’ expectations of rare disasters may also help explain cross-sectional variation in asset returns, while Burnside et al. (2008) and Farhi et al. (2009) argue that peso type problems and disaster risk premia may similarly help justify part of the historically large excess returns to carry trades in the foreign exchange market.
money options and the model-free variation measures originally analyzed in Carr and Wu (2003) further developed here to recover the complete risk-neutral tail jump density.

Our empirical results suggest that on average close to five percent of the equity premium may be attributed to the compensation for rare disaster events. Related option-based estimates for the part of the equity premium due to compensation for jump risk have previously been reported in the literature by Broadie et al. (2007), Eraker (2004), Pan (2002), and Santa-Clara and Yan (2009) among others. However, these earlier studies are all based on fairly tightly parameterized jump-diffusion models and restrictive assumptions about the shapes and dependencies in the tails. Counter to these assumptions, our new non-parametric model-free approach reveals a series of intriguing dynamic dependencies in the tail probabilities, including time-varying jump intensities and a tendency for fatter tails in periods of high overall volatility. At the same time, our results also suggest that the risk premium for tail events cannot solely be explained by the level of the volatility.

In parallel to the equity premium, formally defined by the difference between the statistical and risk-neutral expectation of the aggregate market returns, the variance risk premium is naturally defined as the difference between the statistical and risk-neutral expectation of the corresponding forward variance. The variance risk premium is generally found to be rather large and highly statistically significant. Several recent studies have sought to explain this phenomenon and how the variance premium correlates with the returns; see, e.g., Bakshi and Kapadia (2003), Bakshi and Madan (2006), Bollerslev et al. (2009), Carr and Wu (2009), Drechsler and Yaron (2008), Eraker (2008), and Todorov (2009).

The variance risk premium essentially reflects two types of risks: changes in the investment opportunity set, as manifest by slowly varying stochastic volatility, and the possibility of rare disasters. Taking our analysis one step further, we show that on average more than half of the historically observed variance risk premium is directly attributable to disaster risk, or differences in the jump tails of the risk-neutral and objective distributions. Moreover, while the left and right tails in the statistical distribution are close to symmetric, the contribution to the overall risk-neutral variation coming from the left tail associated with dramatic market declines is several times larger than the variation attributable to the right tail. Our model-free separation of the two types of risk embodied in the variance risk premium thus lends further credence to the common use of the term “investor’s fear gauge” as a moniker for the VIX volatility index; see, e.g., Whaley (1993, 2008).

At a more general level, our results hold the promise of a better understanding of the economics behind the historically large average equity and variance risk premia observed in

---

2Anderson et al. (2003) and Broadie et al. (2007) both forcefully argue from very different perspectives that misspecified parametric models can result in highly misleading estimates for the risk premia. Similarly, Martin (2008) explicitly cautions about inference related to the impact of rare disasters that are overly sensitive to specific parametric modeling assumptions and higher order cumulants.

3Christoffersen et al. (2009) have also recently emphasized the importance of allowing for time-varying jump intensities when modeling S&P 500 returns and options. The discrete-time GARCH model estimates for individual stocks in Maheu and McCurdy (2004) also support the notion of time-varying jump intensities.

4The new model-free VIX volatility index is explicitly designed to mimic the risk-neutral expected one-month-ahead variation of the S&P 500 market index.
the data. Most previous equilibrium based explanations put forth in the literature have effectively treated the two risk premia in isolation, relying on different mechanisms for mapping the dynamics of the underlying macroeconomic fundamentals into asset prices. Instead, our analysis shows that high-frequency aggregate market and derivative prices in combination contain sufficient information to jointly identify both premia in an essentially model-free manner, and that the two premia share a common important source of variation - the fear of rare events. As such, any satisfactory equilibrium based asset pricing model must be able to generate large and time-varying compensations for the possible occurrence of rare disasters.

The plan for the rest of the paper is as follows. We begin in the next section with a discussion of the basic setup and assumptions, along with the relevant formal definitions of the equity and variance risk premia. Section 3 outlines the procedures that we use for separating jumps and continuous price variation under the risk-neutral distribution. Section 4 details the methods that we use for the comparable separation under the statistical measure. Section 5 discusses the data and our initial empirical results. Our main empirical findings related to the tail risks and the risk premia are given in Section 6, including an account of the measures during the recent financial crises. Section 7 reports on various robustness checks related to the dependencies in the tail measures. Section 8 concludes. Most of the technical proofs are deferred to the Appendix, as are some of the details concerning our handling of the options and intraday data, the empirical implementation of the rank robustness tests, and the reduced-form modeling procedure underlying our integrated volatility forecasts.

2 Risk Premia and Jumps

The continuous-time no-arbitrage framework that underly our empirical investigations is extremely general and essentially model-free. It includes all parametric models previously analyzed and estimated in the literature as special cases. We begin with a discussion of the basic setup and notation.

2.1 Setup and Assumptions

To set up the notation, let \( F_t \) denote the futures price for the aggregate market portfolio expiring at some undetermined future date. Also, let the corresponding logarithmic price be denoted by \( f_t \equiv \log (F_t) \). The absence of arbitrage, implies that the futures price should be a semimartingale. Restricting this just slightly by assuming an Itô semimartingale along with jumps of finite variation, the dynamics of the futures price may be expressed as,

\[
\frac{dF_t}{F_t} = \alpha_t dt + \sigma_t dW_t + \int_{\mathbb{R}} (e^x - 1) \tilde{\mu}(dt, dx),
\]

(2.1)

where \( \alpha_t \) and \( \sigma_t \) denote locally bounded, but otherwise unspecified drift and instantaneous volatility processes, respectively, \( W_t \) is a standard Brownian motion. The last term accounts

\footnote{All continuous-time models hitherto used in the literature are Itô semimartingales. The assumption of finite variation for the jumps is inconsequential and for expositional purposes only. The “big” jumps are always of finite activity; i.e., only a finite number over any finite time interval.}
for any jumps, or discontinuities, in the price process through the so-called compensated jump measure \( \tilde{\mu}(dt, dx) \equiv \mu(dt, dx) - \nu^R(dx)dt \), where \( \mu(dt, dx) \) is a simple counting measure for the jumps and \( \nu^R(dx)dt \) denotes the intensity of the jumps.\(^6\) This is a completely general specification, and aside from the implicit weak integrability conditions required for the existence of some of the expressions discussed below, we do not make any further assumptions about the properties of the jumps, or the form of the stochastic volatility process.

The market dynamics described by the statistical \( \mathbb{P} \) measure in equation (2.1) involve two distinct types of risks: the diffusive and jump risk components \( W_t \) and \( \tilde{\mu} \), respectively. The diffusive risk invariably shrinks toward zero over small time intervals. The jumps, on the other hand, always pose a non-trivial risk.

In order to better understand the impact and pricing of these separate risk components, it is instructive to consider the total variation associated with the market price. Specifically, let \( QV_t \) denote the quadratic variation of the log-price process over the \([t, T]\) time-interval,

\[
QV_t \equiv \int_t^T \sigma_s^2 ds + \int_t^T \int_{\mathbb{R}} x^2 \mu(ds, dx).
\] (2.2)

The first term on the right-hand-side represents the variation attributable to the continuous-time stochastic volatility process \( \sigma_s^2 \); i.e., the variation due to “small” price moves. The second term measures the variation due to jumps; i.e., “large” price moves. These risks are fundamentally different and present different challenges from a risk management perspective. While diffusive risks can be hedged/managed by continuously rebalancing a portfolio exposed to those risks, the locally unpredictable nature of jumps means that such a simple strategy will not work when the investor faces jump risk. Therefore, these two types of risks may also demand different compensation, as manifest in the form of different contributions to the aggregate equity and variance risk premia.

### 2.2 Equity and Variance Risk Premia

The equity risk premium represents the compensation directly associated with the uncertainty about the future price level. The variance risk premium refers to the compensation for the risk associated with temporal changes in the variation of the price level.\(^7\)

In particular, let \( \mathbb{Q} \) denote the risk-neutral distribution associated with the general dynamics in equation (2.1). The equity and variance risk premia are then formally defined by,\(^8\)

\[
ERP_t \equiv \frac{1}{T-t} \left( \mathbb{E}_t^\mathbb{P} \left( \frac{F_T - F_t}{F_t} \right) - \mathbb{E}_t^\mathbb{Q} \left( \frac{F_T - F_t}{F_t} \right) \right),
\] (2.3)

\(^6\)Intuitively, this renders the “demeaned” sum of the jumps \( \int_{\mathbb{R}} (e^x - 1) \tilde{\mu}(dt, dx) \) a martingale.

\(^7\)Investors desire to hedge against intertemporal shifts in riskiness has led to the recent advent of many new financial instruments with their payoffs directly tied to various notions of realized price variation. Especially prominent among these are variance swap, or forward, contracts on future realized variances.

\(^8\)From here on we will suppress the dependence on the horizon \( T \) for notational convenience.
and

$$VRP_t \equiv \frac{1}{T-t} \left( E^P_t (QV_{[t,T]}) - E^Q_t (QV_{[t,T]}) \right),$$  \hspace{1cm} (2.4)$$
corresponding to the expected excess return on the market and the expected payoff on a (long) variance swap on the market portfolio, respectively. Empirically, of course, the corresponding sample equity risk premium is generally positive and historically “large”, while the sample variance risk premium as defined above is on average negative and equally “large” and puzzling.\(^9\) Which distributional features account for these well-documented differences in the \(P\) and \(Q\) expectations?

Let \(\nu_t^Q(dx)dt\) denote the compensator, or intensity, for the jumps under \(Q\). Also, let \(\lambda_t\) denote the drift that turns \(W_t\) into a Brownian motion under \(Q\); i.e., \(W_t^Q = W_t + \int_0^t \lambda_s ds\). Standard asset pricing theory implies that all futures (and forward) contracts must be martingales under the risk-neutral \(Q\) measure; see, e.g., Duffie (2001). The drift term for the futures price in the \(P\) distribution in equation (2.1) must therefore satisfy,

$$\alpha_t = \lambda_t \sigma_t + \int_\mathbb{R} (e^x - 1) \nu_t^P(dx) - \int_\mathbb{R} (e^x - 1) \nu_t^Q(dx).$$ \hspace{1cm} (2.5)$$

This general expression directly manifests the compensation that is required by investors to accept the different types of equity price related risks.

Utilizing this result, the wedge between the \(P\) and \(Q\) expectations of the time \(t\) to \(T\) returns and the equity risk premium are naturally decomposed as,

$$ERP_t = ERP_t^c + ERP_t^d,$$ \hspace{1cm} (2.6)$$
where

$$ERP_t^c \equiv \frac{1}{T-t} \left( \int_t^T \frac{F_s}{F_t} \lambda_s \sigma_s ds \right),$$ \hspace{1cm} (2.7)$$
and

$$ERP_t^d \equiv \frac{1}{T-t} \left( \int_t^T \int_\mathbb{R} \frac{F_s}{F_t} (e^x - 1) \nu_s^P(dx) ds - \int_t^T \int_\mathbb{R} \frac{F_s}{F_t} (e^x - 1) \nu_s^Q(dx) ds \right),$$ \hspace{1cm} (2.8)$$
and each of the two terms represent the unique contribution to the premium coming from diffusive and jump risk, respectively.

\(^9\)The equity premium puzzle and the failure of standard consumption-based asset pricing models to explain the sample \(ERP_t\) is arguably one of the most studied issues in academic finance over the past two decades; see, e.g., the discussion in Campbell and Cochrane (1999) and Bansal and Yaron (2004) and the many references therein. Representative agent equilibrium models involving time-separable utility also rule out priced volatility risk and corresponding hedging demands, and in turn imply that \(VRP_t = 0\). Recent rational equilibrium based pricing models designed to help explain the positive variance risk premium by incorporating jumps and/or time varying volatility-of-volatility in the consumption growth process of the representative agent include Bollerslev et al. (2009), Drechsler and Yaron (2008) and Eraker (2008).
Similarly, the variance risk premium may be expressed as,

\[ VRP_t = VRP^c_t + VRP^d_t, \]  

(2.9)

where

\[ VRP^c_t = \frac{1}{T-t}) \left( \mathbb{E}^P_t \left( \int_t^T \sigma^2_s ds \right) - \mathbb{E}^Q_t \left( \int_t^T \sigma^2_s ds \right) \right), \]  

(2.10)

and

\[ VRP^d_t = \frac{1}{T-t}) \left( \mathbb{E}^P_t \left( \int_t^T \int_x x^2 \nu^P_s (dx) ds \right) - \mathbb{E}^Q_t \left( \int_t^T \int_x x^2 \nu^Q_s (dx) ds \right) \right), \]  

(2.11)

represent the diffusive and jump risk components, respectively. As equations (2.10)-(2.11) reveal, due to the presence of jumps we might have variance risk even with i.i.d. returns!\(^{10}\)

The jump risk links directly the equity and variance risk premium. By contrast, the price of diffusive price risk does not enter the variance risk premium. Previous attempts in the literature at trying to separately identify and estimate the risk premia due to jumps have been based on explicit and somewhat restrictive parametric models, in turn resulting in different and sometimes conflicting numerical findings; see, e.g., the discussion in chapter 15 of Singleton (2006). Meanwhile, as equations (2.6) and (2.9) make clear, the compensation for jumps will generally affect the equity and variance risk premia in distinctly different, and statistically identifiable, ways from the way in which the diffusive risk component affect the premia.

In particular, using actual high-frequency data and short maturity options it is possible to non-parametrically estimate,\(^{11}\)

\[ ERP_t(k) = \frac{1}{T-t}) \left( \mathbb{E}^P_t \left( \int_t^T \int_\mathbb{R} \left( e^x - 1 \right) \nu^P_s (dx) ds \right) - \mathbb{E}^Q_t \left( \int_t^T \int_\mathbb{R} \left( e^x - 1 \right) \nu^Q_s (dx) ds \right) \right), \]  

(2.12)

and

\[ VRP_t(k) = \frac{1}{T-t}) \left( \mathbb{E}^P_t \left( \int_t^T \int_\mathbb{R} x^2 \nu^P_s (dx) ds \right) - \mathbb{E}^Q_t \left( \int_t^T \int_\mathbb{R} x^2 \nu^Q_s (dx) ds \right) \right), \]  

(2.13)

\(^{10}\)In addition, one can further separate \( VRP^c_t \) into two components - diffusive and jump-type changes in the stochastic volatility. We do not make this separation for two reasons. First, in this paper our focus is on separating the fears of disasters from the premia attached to changes in the investment opportunity set. The type of changes underlying the evolution of \( \sigma_t \) clearly do not affect such separation. Second, to identify such a decomposition of \( VRP^c_t \), we obviously need some parametric assumptions and this is exactly what we try to avoid in this paper. Parametric evidence from Broadie et al. (2007) indicates most of \( VRP^c_t \) is coming from compensation for jump moves in \( \sigma_t \), while Todorov (2009) finds that the data is not sufficiently informative to make the separation in a semiparametric setting.

\(^{11}\)The integrands in equations (2.8) and (2.12) obviously differ by \( F_s/F_t \). Alternatively, we could have defined the equity risk premium in terms of logarithmic returns, in which case \( F_s/F_t \) will not appear in equation (2.8) either. However, in that case the basic definition would involve convexity adjustment terms.
where $k > 0$ refers to the threshold that separates “big” from “small” jumps.\footnote{The practical choice of $k$ is discussed further in Appendix 9.1 below.} Comparing these estimates with the corresponding estimates for $ERP_t$ with $VRP_t$, we may therefore gauge the importance of fears and rare events in explaining the equity and variance risk premia from directly observable financial data quite generally. We begin our discussion of the empirical procedures with the way in which we quantify the risk-neutral $Q$ distribution and relevant expectations.

\section{Risk-Neutral Measures}

There is long history of using options prices to infer market expectations and corresponding options implied volatilities. Traditionally, these estimates have been based on specific assumptions about the underlying $P$ distribution and the pricing of systematic risk(s). However, as emphasized in the literature more recently, the risk-neutral expectation of the, normalized by the horizon $T - t$, total quadratic variation of the price process in equation (2.2),

$$QV_t^Q \equiv \frac{1}{T-t}E_t^Q \left( \int_t^T \sigma_s^2 ds \right) + \frac{1}{T-t}E_t^Q \left( \int_t^T \int_{\mathbb{R}} x^2 \mu(ds, dx) \right),$$

\label{eq:3.1}

may be estimated in a completely model-free manner by a portfolio of options with different strikes; see, e.g., Bakshi and Madan (2000), Britten-Jones and Neuberger (2000) and Carr and Wu (2009).\footnote{This also mirrors the way in which the CBOE now calculates the VIX volatility index for the S&P 500. The approximation used by the CBOE formally differs from the expression in equation (3.1) by $\frac{1}{T-t}E_t^Q \left( \int_t^T \int_{\mathbb{R}} e^{x^2-1}\left(1-x-x^2\right) \mu(ds, dx) \right)$; for further discussion of the approximation errors involved in this calculation see the white paper on the CBOE website, as well as Carr and Wu (2009) and Jiang and Tian (2005, 2007).} Meanwhile, as the expression in equation (3.1) makes clear, and in parallel to the discussion above, the quadratic variation under $Q$ is naturally decomposed into the expected variation associated with diffusive, or “small” price moves, and discontinuous, or “big” price moves. Building on these insights, we show below how options prices may be used in estimating these two separate parts of the risk-neutral distribution in an essentially model-free fashion.\footnote{Previous attempts at non-parametrically estimating the risk-neutral distribution implied by options prices include Aıt-Sahalia and Lo (1998, 2000), Bakshi and Madan (2000) and Rosenberg and Engle (2002) among others. Aıt-Sahalia et al. (2001) in particular have previously sought to quantify the amount of additional jump risk needed to make the $P$ tails comparable to the options implied $Q$ tails, by calibrating the jump frequency to match the estimated skewness (or kurtosis) of the state price density. To the best of our knowledge, however, none of these studies have sought to estimate the portion of the two risk premia that are directly attributable to the tails of the distribution and the fears of jumps.}

\subsection{Jumps and Tails}

Our estimates for the jump risk perceived by investors are based on close-to-maturity deep out-of-the-money options. The idea of using deep out-of-the-money options to more effec-
tively isolate jump risk has previously been used in the estimation of specific parametric affine jump-diffusion stochastic volatility models by Bakshi et al. (1997), Bates (1996, 2000), Pan (2002) and Eraker (2004) among others, while Pan and Liu (2003) and Pan et al. (2003) have considered similar fully parametric approaches in the context of hedging portfolio jump risks. In contrast to these studies, our estimates for the jump risk premia are entirely non-parametric.

In particular, building on the ideas in Carr and Wu (2003), who used the different rate of decay of the diffusive and jump risk for options with various levels of moneyness as a way to test for jumps, we rely on short-maturity options to actually identify the compensation for jump risk. Intuitively, short-maturity out-of-the-money options will remain worthless unless a rare event, or a “big” jump, occurs before expiration. As such, this allows us to infer the relevant risk-neutral expectations through appropriately scaled option prices.

Specifically, let $C_t(K)$ and $P_t(K)$ denote the price of a call option, respectively put option, with a strike of $K$ recorded at time $t$ expiring at some future date, $T$. It follows that for $T \downarrow t$ and $K > F_t \equiv \lim_{s \uparrow t, s < t} F_s$,

$$e^{r(t, T)} C_t(K) \approx \int_t^T E_t^Q \left( \int_{\mathbb{R}} 1_{\{F_s - x < K\}} (F_s - e^x - K)^+ \nu_s^Q(dx) \right) ds,$$

(3.2)

while for $K < F_t$,

$$e^{r(t, T)} P_t(K) \approx \int_t^T E_t^Q \left( \int_{\mathbb{R}} 1_{\{F_s - x > K\}} (K - F_s - e^x)^+ \nu_s^Q(dx) \right) ds,$$

(3.3)

where $x^+ \equiv \max\{0, x\}$. Importantly, the expressions on the right-hand sides of (3.2) and (3.3) involve only the jump measure. Over short time intervals changes in the price due to the continuous component are invariably small relative to the possible impact of “big” jumps, and the diffusive part may simply be ignored. Moreover, for $T \downarrow t$ there will be at most one “big” jump. The right-hand sides of equations (3.2) and (3.3) represent the conditional expected values of the two different option payoffs under these approximations. The payoffs will be zero if no “big” jump occurred and otherwise equal to the difference between the price after the jump and the strike price of the option.

Going one step further, the expressions in equations (3.2) and (3.3) may be used in the construction of the following model-free risk-neutral jump tails,

$$RT_t^Q(k) \equiv \frac{1}{T - t} \int_t^T \int_{\mathbb{R}} (e^x - e^k)^+ E_t^Q(\nu_s^Q(dx)) ds \approx \frac{e^{r(t, T)} C_t(K)}{(T - t) F_t^\downarrow},$$

(3.4)

and

$$LT_t^Q(k) \equiv \frac{1}{T - t} \int_t^T \int_{\mathbb{R}} (e^k - e^x)^+ E_t^Q(\nu_s^Q(dx)) ds \approx \frac{e^{r(t, T)} P_t(K)}{(T - t) F_t^\downarrow},$$

(3.5)

\[15\]The recent exotic so-called gap options, or gap risk swaps, are explicitly designed to hedge against gap events, or jumps, that is a one-day large price move in the underlying; see Cont and Tankov (2009) and Tankov (2009) for further discussion and theoretical analysis.
where \( k \equiv \ln\left( \frac{K}{F_t} \right) \) denotes the log-moneyness. Unlike the variance replicating portfolio used in the construction of the VIX index and the approximation to \( QV_t \) in equation (3.1), which holds true for any value of \( T \), the approximations for \( RT_t^Q(k) \) and \( LT_t^Q(k) \) in equations (3.4) and (3.5) depend on \( T \downarrow t \).

In practice, of course, we invariably work with close-to-maturity options and a finite horizon \( T - t \), so the effect of the diffusive volatility might be non-trivial. At the same time, the deeper out-of-the-money the options are, the less important the diffusive component. Appendix 9.1 contains a more detailed discussion of the specific criteria that we use in selecting the options underlying our approximations to the two \( Q \) tail measures. As further discussed in that appendix, simulation results designed to mimic our empirical procedures suggest that the error involved in approximating \( LT_t^Q \) through equation (3.5) is in fact quite trivial, while the estimation error for \( RT_t^Q \) in equation (3.4) tend to be somewhat larger. Intuitively, investors primarily fear “big” negative price moves, making the downside jumps in the risk-neutral distribution more pronounced and easier to separate from the diffusive component.

Although the \( RT_t^Q(k) \) and \( LT_t^Q(k) \) measures are related to the tail jump density, they do not directly correspond to risk-neutral expectations required in the calculation of the \( ERP_t(k) \) and \( VRP_t(k) \) jump premia. In order to get at these and the risk-neutral tail density we rely on an additional essentially model-free Extreme Value Theory (EVT) type approximation. This approximation allows us to easily extrapolate the tail behavior from the estimates of \( RT_t^Q(k) \) and \( LT_t^Q(k) \) for a range of different values of \( k \). The only additional assumption required for these calculations concerns the format of the risk-neutral jump density,

\[
\nu_t^Q(dx) = (\varphi_t^+ 1_{\{x>0\}} + \varphi_t^- 1_{\{x<0\}}) \times \nu^Q(x)dx, \tag{3.6}
\]

where the unspecified \( \varphi_t^\pm \) stochastic processes allow for temporal variation in the jump arrivals and \( \nu^Q(x) \) denotes any valid Lévy density. This is a very weak assumption on the general form of the tails, merely restricting the time-variation to be the same across different jump sizes. This assumption is trivially satisfied by all of the previously estimated parametric jump-diffusion models referred to above, most of which restrict \( \varphi_t^\pm \equiv 1 \). Further technical details concerning these calculations are deferred to Appendix 9.4.

The \( ERP_t(k) \) and \( VRP_t(k) \) measures, of course, also depend on the jump tails in the statistical distribution. We next discuss the high-frequency realized variation measures and reduced form forecasting models that we rely on in estimating these.

## 4 Objective Measures

Our estimates of the relevant expectations under the objective, or statistical, probability measure \( \mathbb{P} \) are based on high-frequency intraday data and corresponding realized variation

\[\text{For a general discussion of Extreme Value Theory see, e.g., Embrechts et al. (2001), along with McNeil and Frey (2000) for one of the first empirical applications to financial data with time-varying conditional heteroskedasicy.}\]
measures for the diffusive and dis-continuous components of the total variation in equation (2.2). In addition, we rely on the new EVT-based approximations and nonparametric reduced form modeling procedures for translating the ex-post measurements into forward looking \( P \) counterparts to the \( QV_t^Q \), \( RT_t^Q \), and \( LT_t^Q \) expectations defined above. We begin with a discussion of the high-frequency based realized variation measures and corresponding fill-in asymptotic theory.

### 4.1 Realized Jumps and Volatility

For ease of notation, we normalize the unit time-interval to represent a day, where by convention the day starts with the close of trading on the previous day. The resulting daily \([t, t+1]\) time interval is naturally broken into the \([t, t+\pi_t]\) overnight time period and the \([t+\pi_t, t+1]\) active part of the trading day. The opening time of the market \( t+\pi_t \) is obviously fixed in calendar time. Conceptually, however, it is useful to treat \( \{\pi_t\}_{t=1,2,...} \) as a latent discrete-time stochastic process that implicitly defines the proportion of the total day \( t \) variation due to the overnight price change. With \( n \) equally spaced high-frequency price observations, this leaves us with a total of \( n-1 \) intraday returns for day \( t+1 \) each spanning a time interval of length \( \Delta_{n,t}^i \equiv \frac{1-\pi_t}{n} \), say \( \Delta_{n,t}^i \) if \( f_{t+\pi_t+i\Delta_{n,t}} - f_{t+\pi_t+(i-1)\Delta_{n,t}} \) for \( i = 1, ..., n-1 \).

The realized variation for day \( t \), denoted \( RV_t \), is simply defined as the summation of the squared high-frequency returns over the active part of the trading day. The realized variation measure was formally introduced into the economics and finance literatures by Andersen and Bollerslev (1998), Andersen et al. (2002), and Barndorff-Nielsen and Shephard (2001). The key insight behind the realized variation concept stems from the basic result that for increasingly finer sampled returns, or \( n \uparrow \infty \), \( RV_t \) consistently estimates the total ex-post variation of the price process. Formally,

\[
RV_t \equiv \sum_{i=1}^{n-1} (\Delta_{n,t}^i)^2 \xrightarrow{\mathcal{P}} \int_{t+\pi_t}^{t+1} \sigma_s^2 ds + \int_{t+\pi_t}^{t+1} \int_{\mathbb{R}} x^2 \mu(ds, dx), \tag{4.1}
\]

where the right-hand-side equals the quadratic variation of the price over the \([t+\pi_t, t+1]\) time interval, as defined by the corresponding increment to the total variation in equation (2.2).

As discussed above, the quadratic variation obviously consists of two distinct components: the variation due to the continuous sample price path and the variation coming from jumps. It is possible to separately estimate these two components by decomposing the summation of the squared returns into separate summations of the “small” and “large” price changes.

\(^{17}\)Even though it is useful to conceptually treat the sampling times \((t+\pi_t, t+\pi_t+\Delta_{n,t}, ..., t+1)\) as stochastic, they are obviously fixed in calendar time. As discussed further in the Appendix, all we need from a formal theoretical perspective is for the value of \( \pi_t \) to be (conditionally) independent of the \( f_t \) logarithmic price process.
respectively. In particular, it follows that for the continuous variation

\[ CV_t \equiv \sum_{i=1}^{n-1} (\Delta^n_{t,i} f)^2 1_{\{||\Delta^n_{t,i} f|| \leq \alpha \Delta^n_{\pi,t}\}} \xrightarrow{P} \int_{t+\pi_t}^{t+1} \sigma^2_s ds, \quad (4.2) \]

while for the jump variation

\[ JV_t \equiv \sum_{i=1}^{n-1} (\Delta^n_{t,i} f)^2 1_{\{||\Delta^n_{t,i} f|| > \alpha \Delta^n_{\pi,t}\}} \xrightarrow{P} \int_{t+\pi_t}^{t+1} \int_{\mathbb{R}} x^2 \mu(ds, dx), \quad (4.3) \]

where \( \alpha > 0 \) and \( \varpi \in (0, 0.5) \) denote positive constants.\(^{18}\) These measures for the continuous and jump variation were first proposed by Mancini (2001, 2006). They are based on the intuitive idea that over short time intervals, the continuous component of the price will be normally distributed with variance proportional to the length of the time interval. Thus, if the high-frequency price increment exceeds a certain threshold, it must be associated with a jump in the price.

Building on this same idea, the \( JV_t \) jump component may be further split into the variation coming from positive, or right tail, jumps,

\[ RJV_t \equiv \sum_{i=1}^{n-1} |\Delta^n_{t,i} f|^2 1_{\{\Delta^n_{t,i} f > \alpha \Delta^n_{\pi,t}\}} \xrightarrow{P} \int_{t+\pi_t}^{t+1} \int_{\mathbb{R}} x^2 1_{\{x > 0\}} \mu(ds, dx), \quad (4.4) \]

and negative, or left tail, jumps

\[ LJV_t \equiv \sum_{i=1}^{n-1} |\Delta^n_{t,i} f|^2 1_{\{\Delta^n_{t,i} f < -\alpha \Delta^n_{\pi,t}\}} \xrightarrow{P} \int_{t+\pi_t}^{t+1} \int_{\mathbb{R}} x^2 1_{\{x < 0\}} \mu(ds, dx). \quad (4.5) \]

It follows, of course, by definition that \( RV_t = CV_t + RJV_t + LJV_t. \(^{19}\)

The different ex-post variation measures discussed above all pertain to the actual realized price process. In contrast, the options implied diffusive and jump tail measures discussed in Section 3 provide ex-ante estimates of the risk-neutral expectations of the relevant sources of risks. We next discuss our translation of the actual realized risks into comparable measures of objective, or statistical, ex-ante expectations of these risks.

### 4.2 Expected Jumps and Tails

The most challenging problem in quantifying the statistical expectations in the equity and variance risk premia in equations (2.6) and (2.9), respectively, concerns the \( \mathbb{P} \) equivalent to the previously discussed \( RT_t^0(k) \) and \( LT_t^{12}(k) \) risk-neutral tail measures, say \( RT_t^\varpi(k) \) and

\(^{18}\)The actual choice of \( \alpha \) and \( \varpi \), together with our normalization to account for the strong intraday pattern in the volatility, are discussed in Appendix 9.2.

\(^{19}\)All of the consistency results above may be strengthened to Central Limit Theorems utilizing the results in Jacod (2008).
$LT^p_t(k)$, respectively. These measures pertain to the truly “big” jumps. However, these types of tail events are invariably rare, and possibly even non existent, over a limited calendar time span. This is akin to a Peso type problem, and as such straightforward estimation of the tail expectations based on sample averages will generally not give rise to reliable estimates. Instead, we rely on EVT and the more frequent “medium” sized jumps implicit in the high-frequency intraday data to meaningfully extrapolate the behavior of the “large” jumps, and more precisely estimate the extreme parts of the tails.

A completely general nonparametric approach allowing jumps of different sizes to exhibit arbitrary temporal variation is not practically feasible. However, instead of relying on an explicit parametric model, we merely restrict the temporal variation in the jump intensity to be a linear function of the stochastic volatility,\(^{20}\)

$$\nu_t^p(dx) = \left(\alpha_0^-1_{\{x<0\}} + \alpha_0^+1_{\{x>0\}} + (\alpha_1^-1_{\{x<0\}} + \alpha_1^+1_{\{x>0\}})\sigma_t^2\right) \nu^p(x)dx,$$  \hspace{1cm} (4.6)

where $\nu^p(x)$ is a valid Lévy density, and $\alpha_0^\pm$ and $\alpha_1^\pm$ are nonnegative free parameters. This is a very flexible specification, and we provide direct support for its empirical validity in Section 7. Virtually all parametric models hitherto estimated in the literature have been based on simplified versions of this $\nu_t^p(dx)$ measure, typically restricting $\alpha_1^\pm = 0$. Importantly, the more general specification in equation (4.6) explicitly allows for time-varying jump intensities as a function of the latent volatility process $\sigma_t^2$.\(^{21}\) It also allows for the import of the constant and time-varying intensities to differ across positive and negative jumps.

Compared to conventional fully parametric procedures previously used for estimating the expected impact of jumps, our approach is much more flexible and has the distinct advantage of not relying on a tight connection between the jumps of all different sizes. Indeed, as discussed further below the statistical properties of the “small” and “large” jumps seem to differ quite dramatically, as indirectly evidenced by the markedly different estimates for the tails obtained across competing parametric specifications that utilize all of the jumps, “small” and “large”, for the tail estimation.

Using the flexible assumption about the form of the temporal dependencies in the jump intensity in equation (4.6), the equivalents to the $RT^g_t(k)$ and $LT^g_t(k)$ measures under the statistical distribution, may generally be expressed as

$$RT^p_t(k) = \frac{1}{T-t} \left(\alpha_0^+ + \alpha_1^+ \mathbb{E}_t^p \left(\int_t^T \sigma_s^2ds\right)\right) \int_{\mathbb{R}} (e^x - e^k)^+ \nu^p(x)dx,$$  \hspace{1cm} (4.7)

and

$$LT^p_t(k) = \frac{1}{T-t} \left(\alpha_0^- + \alpha_1^- \mathbb{E}_t^p \left(\int_t^T \sigma_s^2ds\right)\right) \int_{\mathbb{R}} (e^k - e^x)^+ \nu^p(x)dx.$$  \hspace{1cm} (4.8)

\(^{20}\)This parallels the weaker assumption for the risk-neutral jump intensity in equation (3.6). Extensions to allow for nonlinear functions of the volatility or other directly observable state variable are straightforward to implement.

\(^{21}\)Note that $\sigma_t^2$ can, and as the data suggests it does, depend on past realized price jumps so that $\alpha_1^+ > 0$ imply so-called “self-affecting” jumps; see e.g., Todorov (2009).
Thus, in order to estimate $RT^P_t(k)$ and $LT^P_t(k)$, and in turn $QV^P_t$, we only need to quantify the integrals with respect to the Lévy density $\nu^P(x)$, as well as the conditional expectation of the integrated volatility $E^P_t\left(\int_t^T \sigma^2_s ds\right)$.

Our estimates of the integrals with respect to $\nu^P(x)$ are again based on the “medium” sized jumps coupled with EVT for meaningfully extrapolating the behavior of the tails. The separation of the jump intensity into the constant and time-varying part, i.e., $\alpha_0^\pm$ and $\alpha_1^\pm$, respectively, is effectively achieved through the correlation between the occurrence of jumps and past volatility, as measured directly by the realized continuous variation $CV_t$ in equation (4.2). A more detailed description of the relevant calculations are given in Appendix 9.4.

Our estimates for the expected integrated volatility and the time-varying parts of $RT^P_t$, $LT^P_t$ and $QV^P_t$, are based on relatively simple reduced form time series modeling procedures. From a statistical perspective, this is a much easier problem than that of directly estimating the tails as we have plenty of reliable data and previous empirical insights to go by. In particular, it is well established that integrated volatility is a stationary, but highly persistent, process; see, e.g., Bollerslev et al. (2009) and the reduced form model estimates reported therein. It has also previously been documented that jumps in the price tend to be accompanied by jumps in the spot volatility $\sigma_t$, and that negative and positive jumps impact the volatility differently; i.e., a leverage effect through jumps. In order to accommodate all of these non-linear dependencies in the construction of our estimates for the expected integrated volatility, we formulate a Vector Autoregression (VAR) of order 22, or one month, for the four-dimensional vector consisting of $CV_t$, and the additional three state variables $RJV_t$, $LJV_t$, and the squared overnight returns $(f_t - f_{t+n})^2$. To keep the model tractable, we follow the HAR-RV modeling approach of Corsi (2009) and Andersen et al. (2007) and restrict all but the daily, weekly, and monthly lags, or lag 1, 5, and 22, respectively, to be equal to zero. The forecasts for $E^P_t\left(\int_t^T \sigma^2_s ds\right)$ is then simply obtained by recursively iterating the VAR to the relevant horizon. Altogether, this provides a particular convenient and parsimonious approach for capturing the salient dynamic dependencies in the integrated volatility process and corresponding forecasts. Further details concerning the model estimates and forecast construction are given in Appendix 9.5.

Before turning to a discussion of the actual empirical results related to the $P$ and $Q$ tail measures and risk premia estimates, we briefly discuss the data underlying our findings.

## 5 Data and Preliminary Estimates

### 5.1 High-Frequency Data and Statistical Measures

Our high-frequency data for the S&P 500 futures was obtained from Tick Data Inc., and spans the period from January, 1990 to December, 2008. The prices are recorded at five-minute intervals, with the first price for the day at 8:35 (CST) until the last price at 15:15. All-in-all, this leaves us with a total of 81 intraday price observations for each of the 4,751 trading days in the sample.
Time series plots of the corresponding daily realized variation measures in annualized percentage form, following the definitions in Section 4, are given in Figure 1. All of the measures exhibit obvious volatility clustering effects, with a noticeable increase toward the end of the sample and the Fall 2008 financial market crises.

![Figure 1: Realized Measures.](image)

The realized variation measures in turn form the basis for our nonparametric estimates of the statistical expectations of the total quadratic variation and the left and right tail measures, $QV_t^p$, $LT_t^p$ and $RT_t^p$. We will not discuss the details of the estimation results here, instead referring to the Appendix and the actual estimates reported in Tables 6 and 8. Nonetheless, it is instructive to highlight a few of the key empirical findings.

Directly in line with the discussion in the previous section, the stochastic volatility appears to be a highly persistent process. Not only is high volatility predicted by high lagged volatility, negative “realized” jumps also significantly impact future volatility. In contrast to the strong own dynamic dependencies in the volatility, the effect of negative jumps is relatively short-lived, however. Meanwhile, our results also indicate that positive jumps do not affect future volatility. These findings are consistent with the empirical results in Barndorff-Nielsen et al. (2009) and Todorov and Tauchen (2008). They also support a two-factor stochastic volatility model, as in, e.g., Todorov (2009), in which one of the factors is highly persistent, in effect capturing intertemporal shifts in the investment opportunity set, while the other factor is short lived and mainly triggered by (negative) jumps.
Our estimation results also point to the existence of non-trivial temporal variation in the tail jump intensities, as manifest by the highly statistically significant estimates for $\alpha^\pm$. At the same time, the right and left jump tails behave quite similar under the statistical distribution with almost identical tail decays.

Taken as a whole, our empirical results related to the different $\mathbb{P}$ measures indicate much more complicated dependencies than those captured by the specific parametric stochastic volatility models hitherto estimated in the literature. As such, the results further underscore the advantage of the more flexible nonparametric approach adopted here for truly understanding the behavior of the risk premia.

5.2 Options Data and Risk-Neutral Measures

Our options data are obtained from OptionMetrics. The data consists of closing bid and ask quotes for all S&P 500 options traded on the CBOE. The data spans the period from January 1996 till the end of December 2008, for a total of 3,237 trading days. To avoid obvious inconsistencies and problems with the price quotes, we apply the same filters used by Carr and Wu (2003, 2009) for “cleaning” the data.

The estimates for the two tail measures $RT^Q_t(k)$ and $LT^Q_t(k)$ are based on the closest to maturity options for day $t$ with at least eight calendar days to expiration. More specifically, we first calculate Black-Scholes implied volatilities for all out-of-the-money options with moneyness $k$ using linear interpolation of options that bracket the targeted strike. From these implied volatilities we then compute an out-of-the-money option price with moneyness $k$, and in turn the $RT^Q_t(k)$ and $LT^Q_t(k)$ measures as described in Section 3.1 above.

Our calculation of the implied total variance measure $QV^Q_t$, mirrors the approach used by the CBOE in their calculation of the VIX index, as described in the white paper available on the CBOE website. There are two differences, however, between our construction of $QV^Q_t$ and the calculation of the VIX index. First, we rely on trading, or business, time, while the VIX index is constructed using a calendar time convention. Second, for compatibility with the tail measures $RT^Q_t(k)$ and $LT^Q_t(k)$, we use the same closest to maturity options in the calculation of $QV^Q_t$, whereas the VIX is based on linear interpolation of options that bracket a one-month maturity.

The three resulting risk-neutral variation measures are plotted in Figure 2. All of the measures are reported in annualized percentage form. Here and throughout the rest of the analysis, the moneyness for the left and right tails are fixed at 0.9 and 1.1, respectively. As is immediately evident from the figure, the magnitude of the left tail measure substantially exceeds that of the right tail. This, of course, merely reflects the well-known fact that out-of-the-money puts tend to be significantly “overpriced” when assessed by standard pricing models; see, e.g., the discussion in Bates (2009), Bondarenko (2003), Broadie et al. (2009), and Foresi and Wu (2005). Also, all of the three risk-neutral variation measures clearly vary

---

22 The options expire always on a Saturday and the settlement is at the opening of the preceding Friday. Thus an option with 8 calendar days has effectively 4 trading days to its expiration. The median time-to-expiration of the options in our sample is 14 working days.

23 These are taken directly from OptionMetrics and are based on the corresponding mid quotes.
over time, reaching unprecedented levels in Fall 2008. We will study these dynamic patterns, and how they relate to the dependencies in $CV_t$, more closely in Section 7 below.\textsuperscript{24}

\section{Tail Fears and Risk Premia}

We begin our discussion of the equity and variance risk premia and the relationship between the $\mathbb{P}$ and $\mathbb{Q}$ measures in Table 1 with a direct comparison of the average intensity for big jumps under the different measures. In an effort to focus on “normal” times and prevent our estimates of the risk premia and investor fears to be unduly influenced by the recent financial market crises, we explicitly exclude the July 2007 through December 2008 part of the sample from the estimation.

As is immediately evident from Table 1, the estimated frequencies for the occurrences of large jumps are orders of magnitude smaller than the implied jump intensities under the risk-neutral measure. This is consistent with the aforementioned earlier empirical evidence reported in Aït-Sahalia et al. (2001); see their Section 3.5. Since we explicitly rely on the actual, and frequently occurring, “medium-sized” jumps and EVT for meaningfully uncovering the $\mathbb{P}$

\textsuperscript{24}Using the nonparametric EVT-based approximations for the jump tails, detailed in Appendix 9.4, the corresponding estimation results reported in Table 7 confirm that the magnitude of the left tail far exceed that of the right. It also exhibits slightly stronger dynamic dependencies. This asymmetry in the tails under $\mathbb{Q}$ contrasts with the previously discussed approximate symmetric tail behavior under $\mathbb{P}$. 

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure2.png}
\caption{Implied Measures.}
\end{figure}
jump tails, this marked difference cannot easily be “explained” by a standard Peso type problem and a non-representative sample. The table also reveal a strong sense of investor fears, as manifest by the much larger intensities for the left jump tails under $Q$ and the willingness to protect against negative jumps. For instance, the estimated risk-neutral jump intensity for negative jumps less than $-20\%$ is more than twelve times larger than that for positive jumps in excess of $20\%$, and the difference is highly statistically significant. The differences in the left and right $P$ jump tails, on the other hand, are not nearly as dramatic and statistically insignificant.

</tbody>
</table>

Note: The jump intensities are reported in annualized units. The jump sizes are in percentage changes in the price level. The estimates under $Q$ are based on options data from January 1996 through June 2007, while the estimates under $P$ rely on high-frequency futures data from January 1990 through June 2007. Standard errors for the estimates are reported in parentheses. Further details concerning the estimation procedures are provided in Appendix 9.1 and 9.4.

Although the option implied risk-neutral intensities for positive jumps are much smaller than the intensities for negative jumps, they are still much higher than the estimated intensities for positive jumps under the statistical measure. This contrasts with previous estimates from parametric models, which typically imply trivial and even negative premia for positive jumps. Most of these findings, however, have been based on tightly parameterized models that constrain the overall jump intensity, i.e., the intensity for jumps of any size, to be the same under the risk-neutral and statistical measures. Thus, if negative jumps are priced, in the sense that their risk-neutral intensity exceeds their statistical counterpart, this automatically implies that positive jumps will carry no or even a negative risk premium. Meanwhile, our nonparametric approach, which doesn’t restrict the shape and relation between the $P$ and $Q$ jumps, suggest that the large positive jumps do in fact carry a premia, albeit of a much smaller magnitude.\textsuperscript{25} This is also reminiscent of the U-shape pattern in the projection of the pricing kernel on the space of market returns previously documented in A"it-Sahalia and Lo (2000) and Rosenberg and Engle (2002), among others, a possible explanation of

\textsuperscript{25}As discussed further in Section 6.2 below, the temporal variation in the jump intensities means that positive jumps may indeed carry risk premia.
which is provided by the heterogenous agents framework discussed in Bakshi and Panayotov (2009).

Turning next to the actual risk premia, we plot in Figure 3 the components of the equity and variance risk premia that are due to investors fears of rare events; i.e., $ERP(k)$ and $VRP(k)$, respectively. As mentioned before, we explicitly exclude the last eighteen months of the sample in the estimation of the volatility forecasting model and different tail measures, so that the premia in the shaded parts of the figure, coinciding with the advent of the recent financial market crises, are based on the “in-sample” estimates with data through June 2007 only. Also, for ease of interpretation, both of the premia are reported at a monthly frequency based on 22-day moving averages of the corresponding daily estimates.

The time-to-expiration of the options used in the calculation of the risk premia changes systematically over the month, inducing a monthly periodicity in the day-by-day estimates. To illustrate, consider the popular jump-diffusion model of Duffie et al. (2000). For simplicity, suppose there is only a single continuous volatility factor. Let $\kappa^P$ and $\theta^P$ denote the mean-reversion parameter and the mean of $\sigma^2_t$ under $P$, with the corresponding parameters under $Q$ denoted by $\kappa^Q$ and $\theta^Q$. The unconditional mean of the risk premium may then be expressed as $K_0 + K_1(\theta^P - \theta^Q)(1 - e^{-\kappa^Q(T-t)})(\kappa^Q(T-t))^{-1}$, where the two constants $K_0$ and $K_1$ are determined by the risk-premia parameters. This expected premium obviously depends on the horizon and the relative import of the continuous stochastic volatility component, in turn inducing a monthly periodicity in the options implied daily measures.\footnote{The time-to-expiration of the options used in the calculation of the risk premia changes systematically over the month, inducing a monthly periodicity in the day-by-day estimates. To illustrate, consider the popular jump-diffusion model of Duffie et al. (2000). For simplicity, suppose there is only a single continuous volatility factor. Let $\kappa^P$ and $\theta^P$ denote the mean-reversion parameter and the mean of $\sigma^2_t$ under $P$, with the corresponding parameters under $Q$ denoted by $\kappa^Q$ and $\theta^Q$. The unconditional mean of the risk premium may then be expressed as $K_0 + K_1(\theta^P - \theta^Q)(1 - e^{-\kappa^Q(T-t)})(\kappa^Q(T-t))^{-1}$, where the two constants $K_0$ and $K_1$ are determined by the risk-premia parameters. This expected premium obviously depends on the horizon and the relative import of the continuous stochastic volatility component, in turn inducing a monthly periodicity in the options implied daily measures.}
There are obvious similarities in the general dynamic dependencies in the two jump risk premia, with many of the peaks in $ERP(k)$ coinciding with the troughs in $VRP(k)$. At the same time, there are also a number of important differences in the way in which the compensation for the tail events manifest themselves in the two premia. We begin with a more detailed discussion of the equity jump risk premium depicted in the top panel.

6.1 Equity Jump Risk Premium

Most of the peaks in the equity jump risk premium are readily associated with specific economic events. In particular, the October 1997 “mini-crash” and the August-September 1998 turmoil associated with the Russian default and the LTCM debacle both resulted in sharp, but relatively short-lived, increases in the required compensation for tail risks. A similar, albeit much smaller, increase is observed in connection with the September 11, 2001, attacks. Interestingly, the magnitude of the equity jump risk premium in October 2008 is about the same as the premium observed in August-September 1998.

To better understand where this compensation for tail risk is coming from, it is instructive to decompose the total jump risk premium into the parts associated with negative and positive jumps, say $ERP_t^+(k)$ and $ERP_t^-(k)$, respectively. This decomposition, depicted in Figure 4, shows that although the behavior of the two tails are clearly related, the contributions to the overall risk premium are far from symmetric. Most noticeably, the October 1997 “mini-crash” seems to be associated with an increased fear among investors of additional sharp market declines and a corresponding peak in $ERP_t^-(k)$, while there is hardly any effect on $ERP_t^+(k)$. Similarly, the August-September 1998 market turmoil had a much bigger impact on $ERP_t^-(k)$ than it did on $ERP_t^+(k)$. Conversely, the dramatic stock market declines observed in July and September 2002 in connection with the burst of the dot-com “bubble” resulted in peaks and troughs in both $ERP_t^+(k)$ and $ERP_t^-(k)$, with less of a discernable impact on the total jump risk premium $ERP_t(k)$. Likewise, the March 2003 start of the Second Gulf War is hardly visible in $ERP_t(k)$, but clearly influenced both $ERP_t^+(k)$ and $ERP_t^-(k)$. Most dramatic, however, the sharp increase in $ERP_t(k)$ associated with the Fall 2008 financial crises masks even larger offsetting changes in $ERP_t^+(k)$ and $ERP_t^-(k)$ that dwarf the separate jump risk premia observed during the rest of the sample. As such, this directly underscores the popular notion that investors really didn’t know what the “right” price was at the time.

Looking at the typical sample values, again excluding the July 2007-December 2008 part of the sample, the median of the estimated equity risk premia due to fears of rare events equals 5.2%. This is quite high, and compared to the prototypical estimate of 8% for the equity risk premia in postwar U.S. data (see, e.g. Cochrane (2005)), our results imply that fears of rare events account for roughly two-thirds of the total expected excess return. These numbers contrast with the estimation results reported in Broadie et al. (2007), which imply a mean $ERP_t(k)$ of 1.85%, and the estimates in Eraker (2004), which imply a premium for rare events of only 0.65%. Both of these studies, of course, are based on a specific parametric

---

27 Including the more recent period the median increases to 5.6%.
model, whereas our results are essentially model-free and nonparametric.\footnote{The numbers reported in the text are based on the estimates in Broadie et al. (2007) and Eraker (2004) for a stochastic volatility model with correlated jumps, referred to in the literature as a SVCJ type model, in which the parametric form of the jumps effectively implies an exponential decay.}

At a more general level, our findings suggest that excluding fears and tail events, the magnitude of the equity risk premium is quite compatible with the implications from standard consumption-based asset pricing models with “reasonable” levels of risk aversion.\footnote{Conversely, Nieto and Rubio (2008) rely on the volatility of stochastic discount factors from standard consumption-based asset pricing models to back out model implicit notions of economic (recession) fears.} Of course, this raises the question of why investors price tail risk so high? Recent pricing models that pay special attention to tail risks include Pan et al. (2005) and Bates (2008), the work by Bansal and Shaliastovich (2009) and Shaliastovich (2009) based on the concept of confidence risk, and Drechsler (2009) who emphasizes the role of time-varying model uncertainty in amplifying the impact of jumps.

Further corroborating these ideas, we show next that fears of rare events account for an even larger fraction of the historically “large” and difficult to explain variance risk premium.
6.2 Variance Jump Risk Premium

The general dynamic dependencies in the jump variance risk premium depicted in the second panel in Figure 3 fairly closely mirror those of the jump equity premium in the first panel. Similarly, decomposing $\text{VRP}_t(k)$ into the parts associated with negative and positive jumps, say $\text{VRP}_t^+(k)$ and $\text{VRP}_t^-(k)$, respectively, reveal a rather close coherence between the two tail measures. With the notable exception of the aforementioned October 1997 “mini-crash” and the August-September 1998 Russian default and LTCM debacle, most of the spikes coincide between the two time series plotted in Figure 5. The magnitude of $\text{VRP}_t^-(k)$, of course, typically exceeds that of $\text{VRP}_t^+(k)$ by a factor of 2-4.\(^{30}\)

![Graph of VRP^+ and VRP^-](image)

Figure 5: Decomposition of Variance Jump Premia.

Do these findings of large tail risk premia imply a special treatment, or compensation, for rare events? If “large”, i.e., jump-related, risks were treated the same as “small”, i.e., diffusive, risks, what would be the magnitudes of the tail risk premia?

To begin answering these questions, it is instructive to further decompose the variance

\(^{30}\)This is also in line with the recent empirical findings in Andersen and Bondarenko (2009) related to their up and down implied variance measures.
jump tail premia. In particular, from the formal definition of $VRP_t^+(k)$, it follows that

$$
VRP_t^+(k) = \frac{1}{T-t} \left( \mathbb{E}_t^P \int_t^T \int_{x>k} x^2 ds \nu^P_s(dx) - \mathbb{E}_t^Q \int_t^T \int_{x>k} x^2 ds \nu^Q_s(dx) \right)
$$

and

$$
VRP_t^+(k) = 1_T - \mathbb{E}_t^Q \left( \int_t^T \int_{x>k} x^2 ds \nu^P_s(dx) - \int_t^T \int_{x>k} x^2 ds \nu^Q_s(dx) \right),
$$

with a similar decomposition available for $VRP_t^-(k)$. The first term on the right-hand-side reflects the compensation for time-varying jump intensity risk. This part of the tail variance risk premia will be present if and only if the conditional dependencies in the jumps do in fact vary over time. It mirrors the compensation demanded by investors for the continuous part of the quadratic variation, i.e., $VRP_t^c(k)$. As such it is naturally associated with investor’s willingness to hedge against changes in the investment opportunity set. For Lévy type jumps, this part of the variance jump risk premium will be identically equal to zero.

More generally, for the jump intensity process in equation (4.6), the relevant difference between the $\mathbb{P}$ and $\mathbb{Q}$ expectations may be written as,

$$
\mathbb{E}_t^P \int_t^T \int_{x>k} x^2 ds \nu^P_s(dx) - \mathbb{E}_t^Q \int_t^T \int_{x>k} x^2 ds \nu^Q_s(dx) = \alpha^\top \int_{x>k} \nu^P(x) dx \left( \mathbb{E}_t^P \int_t^T \sigma^2_s ds - \mathbb{E}_t^Q \int_t^T \sigma^2_s ds \right).
$$

The format of this expression further highlights the similarity of the first component on the right-hand-side in the expression for $VRP_t^+(k)$ in equation (6.1) with the continuous component $VRP_t^c$ in equation (2.10). In contrast, the second term on the right-hand-side in equation (6.1) involves the wedge between the risk-neutral and objective jump intensities. But, this difference is evaluated under the same probability measure, and as such it is effectively purged of the premia due to temporal variation in the jump intensities. If jumps were treated as diffusive risks, then this component should be zero, since the predictable quadratic variation of the continuous price does not change when changing the measure from $\mathbb{P}$ to $\mathbb{Q}$.

The high-frequency based estimation results discussed in the previous section suggest the existence of significant temporal variation in the tail jump intensities. Part of the tail risk premia will therefore be coming from the first term in equation (6.1). However, our estimation results also suggest that the left and right tails behave quite similarly under $\mathbb{P}$.

In more technical terms, the quadratic variation of the log-price process may be split into its predictable component and a residual martingale component solely due to jumps,

$$
QV_t = \int_t^T \sigma^2_s ds + \int_t^T \int_{x \in \mathbb{R}} x^2 ds \nu^P_s(dx) + \int_t^T \int_{x \in \mathbb{R}} x^2 \tilde{\mu}(ds, dx) \equiv \langle f_s, f_s \rangle_{[t,T]} + \int_t^T \int_{x \in \mathbb{R}} x^2 \tilde{\mu}(ds, dx),
$$

where $\langle f_s, f_s \rangle_{[t,T]}$ denotes the predictable quadratic variation; see, e.g., Jacod and Shiryaev (2003). The pricing of the first term, $\langle f_s, f_s \rangle_{[t,T]}$, is naturally associated with changes in the investment opportunity set, while the pricing of the martingale part reflect any “special” treatment of jump risk.
so that in particular

$$\alpha^+ \int_{x>k} \nu^P(x)dx \approx \alpha^- \int_{x<-k} \nu^P(x)dx.$$ 

Combining this approximation with equation (6.2) and the comparable expression for the left tail measure, it follows that the difference $VRP^-(k) - VRP^+(k)$ will be largely void of the risk premia due to temporal variation in the jump intensities. Consequently, $VRP^+(k) - VRP^-(k)$ may be interpreted as a direct model-free measure of investor fears, or “crash-o-phobia”.

The corresponding plot in Figure 6 shows that the sharpest increase in investor fears over the sample did indeed occur during the recent financial crises. However, the Russian default and LTCM collapse in August-September 1998 resulted in a spike in the fear index almost $2/3$ the size. Slightly less dramatic increases are manifest in connection with the October 1997 ”mini-crash”, September 11, 2001, and the summer of 2002 and the burst of the dot-com “bubble”. The figure also reveals systematically low investor fears from 2003 through mid-2007, corresponding to the general run-up in market values.

Meanwhile, the average sample values reported in Table 2 confirm that much of the variance risk premium does indeed come from “crash-o-phobia”, or special compensation for tail risks. Excluding the post July 2007 crises period, the average sample variance risk

\begin{footnote}{Rubinstein (1994) first attributed the smirk like pattern in post October 1987 Black-Scholes implied volatilities for the aggregate market portfolio when plotted against the degree of moneyness as evidence of “crash-o-phobia”; see also Foresi and Wu (2005) for more recent related international empirical evidence.}

23
premium equals $E(VR P_t) = 0.030$. Of that total premium $E(VR P_t^+(k))/E(VR P_t) = 10.0\%$ may be attributed to compensation for right tail risks, while $E(VR P_t^-(k))/E(VR P_t) = 59.8\%$ comes from left tail risks. In other words, our results suggest that roughly half of the variance risk premium is due to investor fears, as opposed to more standard rational based pricing arguments.

Note: The estimates are reported in annualized form, with standard errors in parentheses. The estimates under $Q$ are based on options data from January 1996 through June 2007, while the estimates under $P$ rely on high-frequency futures data from January 1990 through June 2007. Details concerning the estimation procedure are provided in Appendix 9.4.

Comparing these numbers to the implications from from the aforementioned parametric model estimates reported in the literature, the study by Brodie et al. (2007) imply that $E(VR P_t^+(k))/E(VR P_t) = 24.4\%$, while the results in Eraker (2004) suggest that $E(VR P_t^+(k))/E(VR P_t) = 20.0\%$. These numbers obviously differ quite dramatically from the $10.0\% + 59.8\% = 69.8\%$ obtained with our nonparametric approach. Importantly, however, these and other leading studies have all constrained the wedge between the risk-neutral and statistical jump distributions to a negative shift in the mean jump size; see, e.g., the discussion in Singleton (2006) of these and other related studies, most of which further restrict the analysis to constant jump intensities. The results reported here indicate that the difference in the jump behavior under the two probability measures is much more complex than that, and that time-varying jump intensities play an especially important role for properly understanding and extracting the fear component.

In the next section we further corroborate this idea through a series of robustness checks

---

33These numbers are calculated on the basis of the specific parameter estimates for the SVCJ models reported in the two studies, with the horizon fixed at 14 days, corresponding to the median time-to-expiration of the options used in our analysis, along with $k = 10\%$.

34Broadie et al. (2007) also consider changing the variance of the jumps.
pertaining to the general assumptions concerning the tail dependencies underlying our empirical results and inference procedures.

7 Robustness Checks

Our approach for estimating the risk premia and the contributions from the tails are essentially model-free, the only parametric assumptions relating to the form of the time-varying jump intensities. We begin with a discussion of the $\mathbb{P}$ jump intensities underlying our estimation of the $RT_\mathbb{P}^P(k)$ and $LT_\mathbb{P}^P(k)$ tail measures.

The relevant assumption in equation (4.6) restricts the intensities for the positive and negative jumps to be affine functions, possibly with different coefficients, of the latent instantaneous volatility $\sigma_t^2$. This therefore implies that the left and right realized jump variances, $\int_{t+\pi_t}^{t+1} x^2 \mu(ds,dx)$ and $\int_{t-\pi_t}^{t-1} x^2 \mu(ds,dx)$, only depend upon the past through the temporal variation in the integrated stochastic volatility. Consequently, $\text{Cov}(\int_{t+\pi_t}^{t+1} x^2 \mu(ds,dx), \int_{t-1+\pi_t}^{t-1} \sigma_s^2 ds) = \text{K}_1 \text{Cov}(\int_{t+\pi_t}^{t+1} \sigma_s^2 ds, \int_{t-1+\pi_t}^{t-1} \sigma_s^2 ds)$, and $\text{Cov}(\int_{t+\pi_t}^{t+1} x^2 \mu(ds,dx), \int_{t+\pi_t}^{t+1} \int_{x>0} x^2 \mu(ds,dx)) = \text{K}_1 \text{Cov}(\int_{t+\pi_t}^{t+1} \sigma_s^2 ds, \int_{t-1+\pi_t}^{t-1} \int_{x>0} x^2 \mu(ds,dx))$, where $\text{K}_1 = (\alpha_1^+)^2 \int_{x>0} x^2 \nu^p(x)dx$. Now, defining the vector $Z_t \equiv \left( \int_{t+\pi_t}^{t+1} \sigma_s^2 ds, \int_{t+\pi_t}^{t+1} \int_{x>0} x^2 \mu(ds,dx), \int_{t+\pi_t}^{t+1} \int_{x<0} x^2 \mu(ds,dx) \right)$, it follows that the autocovariance matrix for $Z_t$ should be of reduced rank.\(^{35}\) We state this testable implication in the following proposition.

**Proposition 1** If $\sigma_t^2$ is a covariance stationary and ergodic process, and $\int_{x>0} x^2 \nu^p(x)dx < \infty$. The assumption in equation (4.6) implies that $\text{rank}(\text{Cov}(Z_t, Z_{t-1})) = 1$.

In practice, of course, the vector $Z_t$ is not directly observable. However, as discussed in Section 4.1 above, it may be accurately estimated by $(CV_t, RJV_t, LJV_t)$. Even so, this vector will invariably contain some estimation error, which will render the resulting autocovariance matrix of full rank even if $\text{Cov}(Z_t, Z_{t-1})$ is not. Hence, in order to formally test whether the deviations from reduced rank in the actually observed sample autocovariance matrices for $(CV_t, RJV_t, LJV_t)$ and subsets thereof are statistically significant, we rely on the test developed by Gill and Lewbel (1992). Further details concerning the implementation of the test are given in Appendix 9.3.

\(^{35}\)The possibility of jumps in $\sigma_t^2$ means that the covariance matrix of $Z_t$ will not necessarily be of reduced rank.

Note: The table reports the results of the Gill and Lewbel (1992) rank test, as detailed in Appendix 9.3. The realized variation measures are based on high-frequency futures data from January 1990 through December 2008. The test has a limiting $\chi^2_d$ distribution under the null hypothesis that the autocovariance matrix has reduced rank one. The calculation of the asymptotic variance for the autocovariance matrices are based on a Parzen kernel with a lag-length of 70.

None of the resulting test statistics reported in Table 3 reject the reduced rank hypothesis. These test are based on the realized variation measures over the full sample underlying the different risk premia estimates depicted in the figures, but very similar results are obtained for the January 1990 through June 2007 sample actually used in the tail estimation. As such, the results uniformly support the affine restriction in equation (4.6) related to the actual jump intensities.

In contrast to the affine dependencies for the $\mathbb{P}$ jump intensities underlying our estimates of the statistical tail measures, our estimates for the risk-neutral tail measures rely on the less restrictive condition in equation (3.6). This assumption merely restricts the temporal variation to be the same across different jump sizes, and as such it is trivially satisfied by all parametric models hitherto estimated in the literature. This level of generality for the $\mathbb{Q}$ jump measures may be particularly important to properly accommodate the seemingly complex dynamic dependencies in investor fears.

In order to more formally investigate this hypothesis, suppose that the $\mathbb{Q}$ jump intensities satisfied the analogous affine dependencies assumed for the $\mathbb{P}$ jump measure,

$$\nu^Q_t(dx) = \left(\alpha_0^+ 1_{\{x>0\}} + \alpha_0^- 1_{\{x<0\}} + (\alpha_1^+ 1_{\{x>0\}} + \alpha_1^- 1_{\{x<0\}})\sigma_t^2\right)\nu^Q(x)dx,$$

where $\nu^Q(x)$ denotes a valid Lévy density, and $\alpha_0^+Q$ and $\alpha_1^+Q$ are nonnegative constants. In parallel to the definition of $Z_t$ in Proposition 1 above, define the vector $Y_t = (RT^Q_t(k), LT^Q_t(k), QV^Q_t)'$. If (7.1) holds true, $RT^Q_t(k)$, $LT^Q_t(k)$ and $QV^Q_t$ should all be linear functions of the risk-neutral expected integrated volatility $\mathbb{E}_t^Q\left(\int_t^T \sigma_s^2 ds\right)$. Consequently, the covariance matrix, and equivalently the lag-one autocovariance matrix, for $Y_t$ should be of reduced rank one. If

---

36 We also implemented the same set of tests with all of the variables replaced by their square-roots; i.e., $(CV_{t1/2}^1, RJV_{t1/2}^1, LJV_{t1/2}^1)$. All of these tests strongly rejected the reduced rank hypothesis, highlighting the power of the procedure. Further details of these results are available upon request.

37 This assumption, together with equation (4.6), in turn imply that the temporal variation in all risk premia would be spanned by the level of the stochastic volatility.
(7.1) doesn’t hold, $QV_t^Q$ may still depend linearly on the integrated volatility $E_t^Q \left( \int_t^T \sigma_s^2 ds \right)$. However, in this situation additional time-varying factors will typically affect $Y_t$, so that $\text{rank} \left( \text{Var}(Y_t) \right) \equiv \text{rank} \left( \text{Cov}(Y_t, Y_{t-1}) \right) > 1$. The following testable proposition summarizes this implication.

**Proposition 2** If $Y_t$ is a covariance stationary and ergodic process, and $\int_{|x|>\epsilon} e^{\nu Q(x)} dx < \infty$ for some $\epsilon > 0$. The assumption in equation (7.1) implies that $\text{rank} \left( \text{Cov}(Y_t, Y_{t-1}) \right) = 1$.

The results from the rank tests for the $Q$ tail measures are reported in Table 4. As seen from the table, all of the tests clearly reject the affine structure for the risk-neutral jump intensities. While the tests reported in the table are based on the full sample, including the date through December 2008, very similar results are obtained when excluding the July 2007 through December 2008 part of the sample. This, of course, contrasts with the comparable test results for the $P$ jump intensities in Table 3.

Note: See Table 3. The variation measures are based on options data from January 1996 through December 2008.

Taken as a whole, the robustness tests in Tables 3 and 4 all support the key minimal assumptions underlying our nonparametric inference procedures. At the same time, the results also suggest the existence of much more complex dynamic dependencies in the risk-neutral jump tails than hitherto entertained in the literature, and ones that cannot simply be spanned by the level of the stochastic volatility. As such, this caution against the dangers of falsely restricting the form of the tails to be the same across the $P$ and $Q$ distributions when trying to understand investor fears, or notions of “crash-o-phobia”, embedded in the market prices.

### 8 Conclusion

The recent market turmoil has spurred a renewed interest in the study and economic impact of rare disaster type events. Barro (2009), for instance, argues that the welfare cost of uncertainty and crash fears can be extremely high, and that society as a whole may be willing to forgo almost twenty percent of GDP to eliminate rare disasters.

---

38Barro (2009), for instance, argues that the welfare cost of uncertainty and crash fears can be extremely high, and that society as a whole may be willing to forgo almost twenty percent of GDP to eliminate rare disasters.
occurrence of rare events along with specific parametric modeling assumptions for conducting
the statistical inference. In contrast, the new methodologies developed here are essentially
model-free and nonparametric, relying on high-frequency data and extreme value theory for
effectively measuring the actual tail events, together with a rich set of options for uncovering
the pricing of the tail events.

Allowing the data to “speak for themselves,” our empirical findings suggest that much of
the historically large equity and variance risk premia may indeed be ascribed to compensation
for tail events and are not well described by traditional mean-variance type frameworks.
Excluding the part of the risk premia directly attributable to tail events, the average equity
and variance premia observed in the data are both in line with the general implications from
standard equilibrium based asset pricing models with reasonable preference parameters. Our
decomposition of the variance risk premia further suggests that investors fears, or “crash-
o-phobia”, play a crucial role in explaining the overall magnitude of the tail risk premia.
At the same time, the perception of tail risks appear to vary quite substantially over time,
which may help explain some of the recent sharp movements in market valuations.
9 Appendix

9.1 Estimation of Jump Measures from Options Data

Using the Meyer-Ito formula (Protter (2004), Theorem 70) for the payoff function of out-of-the-money calls, together with the fact that futures prices are martingales under the risk-neutral measure, we can write for $K > F_t$ and $T \downarrow t$ (this result was first derived in Carr and Wu (2003) in the proof of their Theorem 1),

$$e^{r(t,T)}C_t(K) \sim \int_t^T \mathbb{E}_t^Q \left( \int \left[ 1_{\{F_s < K\}}(F_s - e^{x} - K) + 1_{\{F_s > K\}}(K - F_s - e^{x}) \right] \nu_s^Q(dx) \right) ds$$

$$\sim (T - t)F_t - RT_t^Q(k),$$

(9.1)

where $f(x) \sim g(x)$ is to be interpreted as $\lim_{x \to 0} \frac{f(x)}{g(x)} = 1$, and $RT_t^Q(k)$ is formally defined in equation (3.4). A similar result holds for close-to-maturity out-of-the-money puts.

To gauge the magnitude of the approximation errors in equation (9.1) and the comparable equation for the puts in empirical realistic situations with feasible times-to-maturity and levels of moneyness, we simulate data from Merton’s jump-diffusion model. Following Carr and Wu (2003), we fix the interest rate at 5%, the continuous volatility at 14%, the jump intensity at 2, the mean log jump size at $-5\%$, and the volatility of the log jump size at $13\%$.\(^{39}\) The results from the Monte-Carlo simulations are reported in Table 5.

Note: The table reports the estimates for the $e^{r(t,T)}P_t(K)/TF_t - LT_t^Q(k)$ and $e^{r(t,T)}C_t(K)/TF_t - RT_t^Q(k)$ ratios based on simulated data from the Merton jump-diffusion model with the parameter configurations discussed in the text.

As expected, the approximations work best overall for closest-to-maturity and deepest out-of-the-money options. Meanwhile, the left tail is always recovered very accurately, even

\(^{39}\)All of the parameters are reported in annualized units. The only difference from Carr and Wu (2003) is the reduction in the mean log-jump size from $-10\%$ to $-5\%$ to more closely resemble the sample averages observed in our data.
for relatively long-lived and close-to-the-money options. The right jump tail approximation contains somewhat larger errors, especially for longer maturities, or larger $T - t$, and closer to at-the-money, or $k$ close to 0, options. The risk-neutral jump distribution is skewed to the left, making the left jump tail far more dominant and easier to disentangle. All-in-all, however, the results are generally supportive of the approximations that we use for estimating $LT_t^Q(k)$ and $RT_t^Q(k)$.

### 9.2 Estimation of Realized Measures from High-Frequency Data

This appendix provides further details on the computation of the truncation levels that we use in the estimation of $CV_t$, $RJV_t$ and $LJV_t$ in equations (4.2)-(4.5). Theoretically, any $\alpha > 0$ and $\varpi \in (0, 0.5)$ will work. In the actual estimation, however, we fix $\varpi = 0.49$. Our choice of $\alpha$ is a bit more involved and takes into account that volatility changes across days and also has a strong diurnal pattern over the trading day.

To account for the latter feature we estimate nonparametrically a time-of-day factor $TOD_i$, $i=1,2,...,n$,

$$
TOD_i = NOI_i \frac{\sum_{t=1}^{N} (f(t-1+\pi_t)+i\Delta_n,t - f(t-1+\pi_t)+(i-1)\Delta_n,t)^2 \mathbb{1}\{|f(t-1+\pi_t)+i\Delta_n,t - f(t-1+\pi_t)+(i-1)\Delta_n,t| \leq \pi \Delta^0_{49}\}}{\sum_{t=1}^{N} \sum_{i=1}^{M} (f(t-1+\pi_t)+i\Delta_n,t - f(t-1+\pi_t)+(i-1)\Delta_n,t)^2},
$$

(9.2)

where

$$
NOI_i = \frac{\sum_{t=1}^{N} \sum_{i=2}^{n-1} \mathbb{1}\{|f(t-1+\pi_t)+i\Delta_n,t - f(t-1+\pi_t)+(i-1)\Delta_n,t| \leq \pi \Delta^0_{49}\}}{\sum_{t=1}^{N} \sum_{i=2}^{n} \mathbb{1}\{|f(t-1+\pi_t)+i\Delta_n,t - f(t-1+\pi_t)+(i-1)\Delta_n,t| \leq \pi \Delta^0_{49}\}},
$$

and $\Delta_n \equiv \frac{1}{n}$. The truncation level $\overline{\alpha}$ is based on the average volatility in the sample, as measured by the so-called bipower variation measure defined in Barndorff-Nielsen and Shephard (2004). Consequently $\overline{\alpha} \approx \sqrt{(1 - \mathbb{E}(\pi\eta)) \mathbb{E}(\sigma_t^2)}$. The $NOI_i$ factor puts the numerator and denominator in equation (9.2) in the same units. It is approximately equal to $n - 1$. This calculation of $TOD_i$ implicitly assumes that $\pi_t$ and $\sigma_t^2$ are both stationary and ergodic processes. The resulting $TOD_i$ estimates are plotted in Figure 7. The figure shows the previously well-documented U-shape in the average volatility over NYSE trading hours, with separate end effects for the futures before and after the cash market opens; see the discussion in Andersen and Bollerslev (1997) pertaining to a very similar looking picture for an earlier sample period.

To account for the time-varying volatility across days, we use the estimated continuous volatility for the previous day (for the first day in the sample we use $\overline{\alpha}$). Putting all of the pieces together, the time-varying threshold used in our calculations of $CV_t$, $RJV_t$ and $LJV_t$ may be expressed as $\alpha_{t,i} = 3\sqrt{CV_{t-1}} \times TOD_i \times \Delta^0_{49}$.}

30
9.3 Rank Test

We sketch here the basic calculations required for the rank test that we use to test the implications of Propositions 1 and 2. We refer to Gill and Lewbel (1992) for the full details.

Let $A$ denote a general $p \times p$ matrix. The hypothesis of interest may then be expressed as,

$$H_0 : \text{rank}(A) \equiv r \quad \text{vs.} \quad H_1 : \text{rank}(A) > r, \quad r < p,$$

where we have an asymptotically normally distributed estimator of $A$, say

$$\sqrt{N} \text{vec}(\hat{A} - A) \xrightarrow{L} \mathcal{N}(0, V).$$

Also, let $\hat{V}$ denote a consistent estimator of $V$. The rank test is based on LDU (lower-diagonal-upper triangular) decomposition with complete pivoting; i.e., the elements of the diagonal matrix are decreasing in absolute value. To this end we write the matrices associated with this decomposition as

$$\hat{P} \hat{A} \hat{Q} = \hat{L} \hat{D} \hat{U},$$

where

$$\hat{L} = \begin{pmatrix} \hat{L}_{11} & 0 \\ \hat{L}_{21} & I_{p-r} \end{pmatrix}, \quad \hat{D} = \begin{pmatrix} \hat{D}_1 & 0 \\ 0 & \hat{D}_2 \end{pmatrix}, \quad \hat{U} = \begin{pmatrix} \hat{U}_{11} & \hat{U}_{12} \\ 0 & \hat{U}_{22} \end{pmatrix}$$

and $\hat{P}$ and $\hat{Q}$ are permutation matrices, $\hat{L}_{11}$, $\hat{U}_{11}$ and $\hat{U}_{22}$ are unit lower triangular, and in addition

$$\hat{H} = [-\hat{L}_{22}^{-1} \hat{L}_{21} \hat{L}_{11}^{-1} \hat{L}_{22}^{-1} 0] \quad \hat{K} = \begin{pmatrix} -\hat{U}_{11}^{-1} \hat{U}_{12} \hat{U}_{22}^{-1} \\ \hat{U}_{22}^{-1} \end{pmatrix}.$$
Further, let $\Xi_i$ denote the $(p - r) \times (p - r)$ matrix with ones along the i-th diagonal and zeros everywhere else, and define

$$\Xi = \begin{pmatrix} \Xi_1 \\ \vdots \\ \Xi_n \end{pmatrix},$$

and

$$\widehat{W} = \Xi' (\widehat{K}' \otimes \widehat{H}) (\widehat{Q}' \otimes \widehat{P}) \widehat{V} (\widehat{Q} \otimes \widehat{P})' (\widehat{K} \otimes \widehat{H}') \Xi.$$

Finally, let $\hat{d}_2 = \text{diag}(\hat{D}_2)$. The rank test is then given by

$$N \hat{d}_2 \widehat{W}^{-1} \hat{d}_2 \overset{\text{approx}}{\sim} \chi^2_{p-r}.$$

### 9.4 Estimation of Jump Tails

We start with some general remarks that apply for both the $\mathbb{P}$ and $\mathbb{Q}$ distributions, and then subsequently specialize the discussion to the statistical and risk-neutral jump tail estimation. For ease of notation, we will suppress the dependence on $\mathbb{P}$ and $\mathbb{Q}$ in the Lévy densities $\nu^\mathbb{P}(x)$ and $\nu^\mathbb{Q}(x)$ in this initial discussion.

To begin, define $\psi^+(x) = e^x - 1$ for $x \in \mathbb{R}_+$ and $\psi^-(x) = e^{-x}$ for $x \in \mathbb{R}_-$. $\psi^+(x)$ maps $\mathbb{R}_+$ into $\mathbb{R}_+$, and $\psi^-(x)$ maps $\mathbb{R}_-$ into $(1, +\infty)$. Both mappings are one-to-one. Further, denote $\nu^+_\psi(y) = \frac{\nu(\ln(y + 1))}{y+1}$ for $y \in (0, \infty)$ and $\nu^-_\psi(y) = \frac{\nu(-\ln y)}{y}$. It follows then for every measurable set $A$ in $(0, \infty)$ that $\int_{(0,\infty)} 1_{\{x \in A\}} \nu^+_\psi(x) dx = \int_{\mathbb{R}_+} 1_{\{e^x-1 \in A\}} \nu(x) dx$. Similarly, for every measurable set $A$ in $(1, \infty)$, we have that $\int_{(1,\infty)} 1_{\{x \in A\}} \nu^-_\psi(x) dx = \int_{\mathbb{R}_-} 1_{\{e^{-x} \in A\}} \nu(x) dx$. Finally, denote the tail jump measures

$$\overline{\nu}^\pm_\psi(x) = \int_{x}^{\infty} \nu^\pm_\psi(u) du,$$

with $x > 0$ for $\overline{\nu}^+_\psi(x)$, and $x > 1$ for $\overline{\nu}^-_\psi(x)$.

Our estimation of the jump tails is nonparametric, and based on the assumption that the tail Lévy densities $\overline{\nu}^-_\psi$ and $\overline{\nu}^+_\psi$ belong to the domain of attraction of an extreme value distribution; see, e.g., the general discussion in Embrechts et al. (2001), along with the recent empirical analysis related to extreme market moves in Bakshi et al. (2009). This is a vary wide class of jump measures, and it includes most parametric specifications that have previously been used in the literature. This assumption in turn implies that $\overline{\nu}^\pm_\psi = x^{-p} L(x)$ for some $p$ and slowly varying at infinity function $L(x)$; i.e., a function with the property that $\lim_{x \to \infty} \frac{L(tx)}{L(x)} = 1$ for every $t > 0$. This, of course, does not pin down the tail Lévy measure itself, as the function $L(x)$ is unknown. However, under additional mild technical assumptions on the function $L(x)$, see, e.g., Smith (1987), we have that

$$1 - \frac{\overline{\nu}^\pm_\psi(u+x)}{\overline{\nu}^\pm_\psi(x)} \overset{\text{approx}}{\sim} G(u; \sigma^\pm, \xi^\pm), \quad u > 0, x > 0,$$

where

$$32$$
where
\[
G(u; \sigma^\pm, \xi^\pm) = \begin{cases} 
1 - (1 + \xi^\pm u/\sigma^\pm)^{-1/\xi^\pm}, & \xi^\pm \neq 0, \sigma^\pm > 0 \\
1 - e^{-u/\sigma^\pm}, & \xi^\pm = 0, \sigma^\pm > 0
\end{cases}
\] (9.5)

\(G(u; \sigma^\pm, \xi^\pm)\) is the cdf of a \textit{generalized Pareto distribution}. In what follows we assume that the approximation in (9.4) is exact when \(x\) is large enough; see the formal proofs in Bollerslev and Todorov (2009) for further details concerning the approximation error and the exact conditions under which the error is asymptotically negligible.

Before we turn to our discussion of the estimation of the parameters for the generalized Pareto distribution approximation to the tail Lévy densities for the statistical and risk-neutral distributions, we present several integrals with respect to the Lévy density \(\nu(x)\) that appear in \(ERP_t(k), VRT_t^\rho(k), LT_t^\rho(k), RT_t^\rho(k)\) and \(LT_t^\xi(k)\). In particular, assuming that the approximation in (9.4) holds, it follows that for \(k > 0\) and some \(tr^+ < e^k - 1\),

\[
\int_{x>k} (e^x - 1) \nu(x) dx = (e^k - 1) \nu^+_\psi(e^k - 1) + \int_{\mathbb{R}} (e^x - e^k)^+ \nu(x) dx,
\]

\[
\int_{\mathbb{R}} (e^x - e^k)^+ \nu(x) dx = \int_{(0, \infty)} (x - e^k + 1)^+ \nu^+_\psi(x) dx = \int_{e^k - 1}^\infty \nu^+_\psi(x) dx
\]

\[
= \nu^+_\psi(tr^+) \int_{e^k - 1}^\infty \left(1 - \frac{\nu^+_\psi(x)}{\nu^+_\psi(tr^+)}\right) dx
\]

\[
= \nu^+_\psi(tr^+) \left(\frac{\sigma^+}{1 - \xi^+}\right) \left(1 + \frac{\xi^+}{\sigma^+}(e^k - 1 - tr^+)\right)^{1-1/\xi^+},
\]

\[
\int_{x>k} (e^x - 1 - x) \nu(x) dx = \int_{x>e^k-1} (x - \ln(x + 1)) \nu^+_\psi(x) dx
\]

\[
= \nu^+_\psi(e^k - 1)(e^k - 1 - k) + \nu^+_\psi(tr^+) \frac{\sigma^+}{1 - \xi^+} \left(1 + \frac{\xi^+}{\sigma^+}(e^k - 1 - tr^+)\right)^{1-1/\xi^+}
\]

\[
- \frac{\nu^+_\psi(tr^+)\sigma^+^{1/\xi^+}\xi^+}{(e^k\xi^+)^{1/\xi^+}} 2F_1 \left(\frac{1}{\xi^+}; \frac{1}{\xi^+}; 1 + \frac{\xi^+}{\sigma^+}(tr^+ + 1) - 1, \frac{\xi^+}{\sigma^+}e^k\right),
\]

\[
\int_{x>k} x^2 \nu(x) dx = k^2 \nu^+_\psi(e^k - 1) + 2 \int_{x>e^k-1} \frac{\ln(x + 1)}{x + 1} \nu^+_\psi(x) dx = k^2 \nu^+_\psi(e^k - 1) + 2\nu^+_\psi(tr^-) \times K_1,
\]

\[
K_1 = e^{-k/\xi^+\xi^+} \left(\frac{\xi^+}{\sigma^+}\right)^{-1/\xi^+} \left[3F_2 \left(\frac{1}{\xi^+}; \frac{1}{\xi^+}; 1 + \frac{1}{\xi^+}; \frac{\xi^+}{\sigma^+}(tr^+ + 1) - 1, \frac{\xi^+}{\sigma^+}e^k\right) + 2F_1 \left(\frac{1}{\xi^+}; \frac{1}{\xi^+}; 1 + \frac{\xi^+}{\sigma^+}(tr^+ + 1) - 1, \frac{\xi^+}{\sigma^+}e^k\right)\right],
\]

where \(3F_2(\ , \ , \ ; \ , \ ; \ )\) and \(2F_1(\ , \ , \ ; \ )\) are the hypergeometric functions. The above integrals are all well defined provided that \(\int_{x>e^\epsilon} x^2 \nu^+_\psi(x) dx < \infty\) for some \(\epsilon > 0\), i.e. \(\xi^+ < 1\). Similar calculations for \(k < 0\) and \(1 < tr^- < e^{-k}\) yield,

\[
\int_{x<k} (e^x - 1) \nu(x) dx = (e^k - 1) \nu^+_\psi(e^k) - \int_{\mathbb{R}} (e^k - e^x)^+ \nu(x) dx,
\]

33
9.4.1 Estimation of $P$

The resulting parameter vector that we seek to estimate is therefore throughout this subsection we will assume that the $\nu$ estimating equations,

$$
\int_{(0, \infty)} (e^k - x^+ \nu(x)dx = \int_{\infty}^{\frac{\nu}{e^{-k} x}} \nu(x)dx = \int_{e^{-k} x}^\infty \frac{\nu(x)}{x^2}dx
$$

$$
= \nu_\psi(\nu^-) \left( \frac{\xi^-}{\xi^- + 1} \right) \left( e^k \right)^{1+1/\xi^-} \left( \frac{\xi^-}{\sigma^-} \right)^{-1/\xi^-}
$$

$$
\times 2F_1 \left( 1 + \frac{1}{\xi^-}; \frac{1}{\xi^-}; 2 + \frac{1}{\xi^-}; -\frac{1}{e^{-k} \frac{\xi^-}{\sigma^-}} \right),
$$

$$
\int_{x<k} (e^k - x)\nu(x)dx = \int_{x>e^{-k}} \left( \frac{1}{x} - 1 + \ln x \right) \nu_\psi(x)dx
$$

$$
= \nu_\psi(e^{-k})(e^k - 1 - k) + \nu_\psi(\nu^-) \left( e^k \frac{1}{\xi^-} \right)^{1/\xi^-} \xi^- \times K_2,
$$

$$
K_2 = 2F_1 \left( \frac{1}{\xi^-}, \frac{1}{\xi^-}; 1 + \frac{1}{\xi^-}; \frac{e^{-k} \frac{\xi^-}{\sigma^-} - 1}{\xi^-} \right) - e^{\frac{k}{\xi^-}} + 2F_1 \left( 1 + \frac{1}{\xi^-}; \frac{1}{\xi^-}; 2 + \frac{1}{\xi^-}; \frac{1}{e^{-k} \frac{\xi^-}{\sigma^-}} \right),
$$

$$
\int_{x<k} x^2\nu(x)dx = k^2\nu_\psi(e^{-k}) + 2 \int_{x>e^{-k}} \frac{\ln(x)}{x} \nu_\psi(x)dx = k^2\nu_\psi(e^{-k}) + 2\nu_\psi(\nu^-) \times K_3,
$$

$$
K_3 = e^{k/\xi^-} \left( \frac{\xi^-}{\sigma^-} \right)^{-1/\xi^-} \left[ 2\nu_\psi \left( \frac{1}{\xi^-}, \frac{1}{\xi^-}; \frac{1}{\xi^-}; 1 + \frac{1}{\xi^-}; \frac{1}{e^{-k} \frac{\xi^-}{\sigma^-}} \right) - k_2F_1 \left( \frac{1}{\xi^-}; \frac{1}{\xi^-}; 1 + \frac{1}{\xi^-}; \frac{\xi^- - \nu^- - 1}{e^{-k} \frac{\xi^-}{\sigma^-}} \right) \right].
$$

9.4.1 Estimation of $P$ Jump Tails

Throughout this subsection we will assume that the $P$ Lévy measure satisfies equation (4.6).

The resulting parameter vector that we seek to estimate is therefore

$$
\theta \equiv \left( \sigma^\pm, \xi^\pm, \alpha^\pm \nu_\psi(\nu^-), \alpha^\pm \nu_\psi(\nu^\pm), \pi \right),
$$

where $\pi \equiv E(\pi_t)$. We base our estimation on the scores associated with the log-likelihood function of the generalized Pareto distribution,

$$
\phi_1^\pm(u) = -\frac{1}{\sigma^\pm} + \frac{\xi^\pm u}{(\sigma^\pm)^2} \left( 1 + \frac{1}{\xi^\pm} \right) \left( 1 + \frac{\xi^\pm u}{\sigma^\pm} \right)^{-1},
$$

$$
\phi_2^\pm(u) = \frac{1}{(\xi^\pm)^2} \ln \left( 1 + \frac{\xi^\pm u}{\sigma^\pm} \right) - \frac{u}{\sigma^\pm} \left( 1 + \frac{1}{\xi^\pm} \right) \left( 1 + \frac{\xi^\pm u}{\sigma^\pm} \right)^{-1}.
$$

Following Bollerslev and Todorov (2009), this naturally give rise to the following set of estimating equations,

$$
E \left( \int_{t+\pi_i}^{t+\pi_i} \phi_i^\pm(\psi^\pm(x) - tr^\pm)1_{\psi^\pm(x) > tr^\pm} \mu(ds, dx) \right) = 0, \quad i = 1, 2,
$$

34
\[
\begin{align*}
\mathbb{E} \left( \int_{t+\pi_t}^{t+1} \int_{\mathbb{R}} 1_{\{\psi^+(x) > tr^+\}} \mu(ds, dx) - (1 - \pi) \alpha_0^+ \varphi^+_\psi(tr^+) - \alpha_1^+ \varphi^+_{\psi}(tr^+) \int_{t+\pi_t}^{t+1} \sigma^2_s ds \right) &= 0, \\
\mathbb{E} \left( \int_{t+\pi_t}^{t+1} \int_{\mathbb{R}} 1_{\{\psi^-(x) > tr^-\}} \mu(ds, dx) - (1 - \pi) \alpha_0^- \varphi^-_\psi(tr^-) - \alpha_1^- \varphi^-_{\psi}(tr^-) \int_{t+\pi_t}^{t+1} \sigma^2_s ds \right) &= 0, \\
(1 - \pi) \mathbb{E} (f_{t+\pi_t} - f_t)^2 - \pi \mathbb{E} \left( \int_{t+\pi_t}^{t+1} \sigma^2_s + \int_{t+\pi_t}^{t+1} \int_{\mathbb{R}} x^2 \mu(ds, dx) \right) &= 0.
\end{align*}
\]

In order to operationalize these equations, we substitute all of the expectations with their sample analogues constructed from the high-frequency data,

\[
\frac{1}{N} \sum_{t=1}^{N} \sum_{j=1}^{n-1} \phi^+_t \left( \psi^+_\left( \Delta_{n,t}^-p \right) - tr^+ \right) 1_{\{\psi^+_\left( \Delta_{n,t}^-p \right) > tr^+ \}} = 0, \quad i = 1, 2,
\]

\[
\frac{1}{N} \sum_{t=1}^{N} \sum_{j=1}^{n-1} 1_{\{\psi^-\left( \Delta_{n,t}^+p \right) > tr^- \}} - (1 - \pi) \alpha_0^- \varphi^-_\psi(tr^-) - \alpha_1^- \varphi^-_{\psi}(tr^-) CV_t = 0,
\]

\[
\frac{1}{N} \sum_{t=2}^{N} \sum_{j=1}^{n-1} 1_{\{\psi^+\left( \Delta_{n,t}^+p \right) > tr^+ \}} - (1 - \pi) \alpha_0^+ \varphi^+_\psi(tr^+) - \alpha_1^+ \varphi^+_{\psi}(tr^+) CV_t \right) CV_{t-1} = 0,
\]

\[
(1 - \pi) \frac{1}{N} \sum_{t=1}^{N} (p_{t+\pi_t} - p_t)^2 - \pi \frac{1}{N} \sum_{t=1}^{N} RV_t = 0.
\]

The only remaining issue relates to the choice of \( tr^\pm \). On the one hand, high thresholds are preferred so that the asymptotic extreme value approximation in (9.4) works best. On the other hand, we need sufficiently many jumps above the thresholds to make the estimation reliable. Faced with this tradeoff, we set the values for \( tr^\pm \) so that they correspond to jumps in the log-prices of 0.6\%. In the sample we have 229 such jumps; 127 of them negative and 102 of them positive. This choice for \( tr^\pm \) exceed the maximum threshold value for \( \alpha_{t,i} \) used in the construction of \( CV_t \) and \( JV_t \), so that the continuous component in the price will have negligible effect in our estimation.

</tr>
</tbody>
</table>

Note: \( tr^- = e^{-0.006} \approx 0.994 \) and \( tr^+ = e^{0.006} - 1 \approx 0.006 \). The estimates are based on high-frequency futures data from January 1990 through June 2007.
The results from the estimation are reported in Table 6. As discussed in the main text, the $\mathbb{P}$ tails are clearly time-varying, but otherwise appear close to symmetric. Not reported in the table, our estimate for $\pi \equiv \mathbb{E}(\pi_t)$ equal to $0.2076(0.0448)$ implies that on average roughly nineteen percent of the total variation is due to changes in the price during non-trading hours.

### 9.4.2 Estimation of $\mathbb{Q}$ Jump Tails

Our estimation of the jump tail probabilities under $\mathbb{Q}$ only requires the weak separability condition for the time dependence and jump sizes implicit in the Lévy density in equation (3.6). The parameter vector that we seek to estimate is

$$\theta \equiv \left( \sigma_Q^+, \xi_Q^+, \alpha_Q^+, \varphi_Q^+(tr^+) \right).$$

From the calculations at the beginning of this section, we have that for $0 < tr^+ \leq e^k - 1$,

$$E \left( RT_Q^+(k) \right) = \alpha_Q^+ \varphi_Q^+(tr^+) \frac{\sigma_Q^+}{1 - \xi_Q^+} \left( 1 + \frac{\xi_Q^+}{\sigma_Q^+} (e^k - 1 + tr^+) \right)^{1 - 1/\xi_Q^+},$$

while for $1 < tr^- \leq e^{-k}$,

$$E \left( LT_Q^-(k) \right) = \alpha_Q^- \varphi_Q^-(tr^-) \frac{\xi_Q^-}{\xi_Q^- + 1} \left( e^k \right)^{1 + 1/\xi_Q^-} \left( \frac{\xi_Q^-}{\sigma_Q^-} \right)^{-1/\xi_Q^-} \times 2F_1 \left( 1 + \frac{1}{\xi_Q^-}; \frac{1}{\xi_Q^-}; 2 + \frac{1}{\xi_Q^-}; \frac{tr^- - \xi_Q^-}{\sigma_Q^-} - 1; e^{-k} \frac{\xi_Q^-}{\sigma_Q^-} \right),$$

where $\alpha_Q^+ \equiv E \left( \frac{1}{\tau - t} \mathbb{E}_t^\mathbb{Q} \left( \int_t^T \varphi_s^+ ds \right) \right)$ and $\alpha_Q^- \equiv E \left( \frac{1}{\tau - t} \mathbb{E}_t^\mathbb{Q} \left( \int_t^T \varphi_s^- ds \right) \right)$.

Now replacing the unconditional risk-neutral expectations of the jump tail measures with the sample analogues of $RT_Q^+(k)$ and $LT_Q^-(k)$ for three different levels of moneyness for each of the tails results in an exactly identified GMM estimator. The levels of moneyness that we use in the estimation are $K_{Ft^-} = 0.9250, 0.9125,$ and $0.9000$ for the left tail, and $K_{Ft^+} = 1.0750, 1.0875$, and $1.1000$ for the right tail. These levels of moneyness are sufficiently “deep” in the tails to guarantee that the effect of the diffusive price component in measuring $LT_Q^-(k)$ and $RT_Q^+(k)$ is minimal, and that the extreme value asymptotic distribution provides a good approximation to the tail jump probabilities. The truncation levels are fixed at $tr^- = \frac{1}{1 - 0.075}$ for the left tail and $tr^+ = 0.075$ for the right tail. This corresponds directly to the moneyness for the closest-to-the-money options used in the estimation.

The results from the estimation are reported in Table 7. Not only is the left tail under the $\mathbb{Q}$ distribution at a higher level, it also decays at a slower rate. Although not directly comparable, the standard errors for the $\mathbb{Q}$ tail parameters are much smaller than the ones for the $\mathbb{P}$ tail parameters reported in Table 6. This is quite intuitive as our estimation
Table 7: Estimates for $\mathbb{Q}$ Tail Parameters

</table>

Note: The estimates are based on options data from January 1996 through June 2007.

for the risk-neutral distribution are based on expectations for the “large” jumps, while the estimates for the statistical distribution rely on actual realizations of “large” jumps in the high-frequency data for inferring the relevant expectations, thus inducing an extra layer of estimation error uncertainty.

9.5 Estimation of Expected Integrated Volatility

Our estimation of $\mathbb{E}_t \left( \int_t^T \sigma_s^2 ds \right)$ is based on the following restricted 22-order Vector Autoregression,

$$
X_t = A_0 + A_1 X_{t-1} + A_5 \sum_{i=1}^5 X_{t-i}/5 + A_{22} \sum_{i=1}^{22} X_{t-i}/22 + \epsilon_t,
$$

for the four-dimensional vector

$$
X_t \equiv \left( CV_t \quad RJV_t \quad LJV_t \quad (p_{t+\pi} - p_t)^2 \right)'.
$$

The multi-period expected integrated volatility is calculated from the sum of the relevant forecasts for the first element in $X_t$, which in turn are easily constructed by recursive linear projections using the Kalman filter.

The resulting parameter estimates for the VAR are reported in Table 8. Not surprisingly, the estimates for the $(1, 1)$ elements in the $A_1$, $A_5$ and $A_{22}$ matrices point to the existence of strong own persistence in the continuous volatility component. The estimates also reveal significant asymmetries in the dynamic dependencies between the continuous volatility and the tails and the overnight returns, underscoring the importance of including these variables in the construction of the integrated volatility forecasts.
